(Sonja Wiedemann)

## Acknowledgements

First of all I want to thank Dr. Sandra Hake for giving me the opportunity to work on this very exciting project, for always finding time for discussions, even in busy times, for giving useful scientific input, never running out of ideas when the project was stuck and for letting me find my own way. Thank you for being a boss when I needed a boss and a friend when I needed a friend. You are doing a great job!

I am grateful to Prof. Dr. Peter Becker for always having time for me, for his advice and constant support and for providing not only a scientifically motivating environment but also a perfect lab atmosphere.

I also want to express my gratitude to the other members of my thesis advisory committee, Prof. Gunnar Schotta and Prof. Stefan Jentsch, for their time and helpful comments.

Heartfelt thanks go to all members of the Hake group for creating the perfect mixture between science and fun in the lab. Thank you for endless discussions about scientific problems, for always taking over when help was needed, for constantly emptying the candy drawer ("I was running this morning") and for simply being my friends!

I also would like to thank all past and present members of the molecular biology department for creating a scientifically motivating environment, help whenever needed, discussions and criticism and of course for the fun.

I would like to acknowledge my collaborators for their excellent experimental contribution and scientific interest, especially Silke Mildner, Clemens Bönisch, Sarah Matheisl, Lars Israel, Tobias Straub, Lothar Schermelleh, Heinrich Leonhardt, Elisabeth Kremmer und Rainer Merkl.

For technical help, reagents and cell lines, I want to thank Christiane Simon, Sandra Venegasalam, Mariacristina Chioda, Ignasi Forné, Martin Heidemann, Corinna Hintermair, Robert Löwe, Stefan Müller and Marion Cremer.

My special thanks go to my husband Thomas, thank you for always being there for me.

# Summary

Chromatin is the packaged form of DNA in the eukaryotic nucleus, with the nucleosome as its basic unit. The nucleosome consists of DNA, wrapped around a histone octamer which is comprised of two copies of each of the four core histones H2A, H2B, H3 and H4. To allow DNA-related processes to occur, access to the DNA has to be regulated. One regulatory mechanism is the exchange of the canonical core histones by one of their replacement variants. Thus far, five members of the histone H3 family have been described: H3.1, H3.2, H3.3, testis-specific tH3 and centromere-specific CENP-A. Searching the database, we have recently identified two novel histone H3 variant genes on human chromosome 5, now termed *H3.X* and *H3.Y*. In my PhD thesis, I have analyzed their expression patterns, characterized their mRNA as well as their protein products and investigated their potential function(s).

*H3.X* and *H3.Y* constitute primate-specific genes which have been found, in addition to humans, also in the chimpanzee and the macaque, but not in other mammals or even lower eukaryotes. H3.X and especially H3.Y mRNA is expressed at low but significant levels in the human osteosarcoma cell line U2OS and in some human bone, breast, lung and ovary tumor tissues, as well as in testis and certain areas of the brain. Tagged H3.X and H3.Y proteins behave similar to H3.1, H3.2 and H3.3 in their nuclear localization and stable incorporation into chromatin. However, in contrast to H3.1 and H3.3, novel H3 variants primarily form heterotypic nucleosomes. Endogenous H3.Y protein is expressed in a small number of U2OS cells (<0.1%), localizes to the nucleus and constitutes a stable chromatin component. The number of H3.Y-expressing U2OS cells can be increased by specific stress conditions, such as nutritional stress paired with high cell density. Matching its expression pattern in U2OS cells, H3.X and/or H3.Y protein(s) have also been observed in a small subpopulation of neurons in the human hippocampus. H3.Y has an influence on the expression of certain genes, most of them being implicated in regulating the cell cycle and chromatin structure. In line with this finding, knockdown of H3.X and H3.Y impairs cell growth.

In conclusion, the results of this work show that H3.Y (and maybe H3.X) are novel primate-specific histone H3 variants which play a role in cell cycle regulation. Their expression is induced by certain stress stimuli and their presence in brain and testis suggests a potential role in primate-specific brain functions and speciation.

# Zusammenfassung

Chromatin ist die Verpackungsform der DNS im eukaryontischen Zellkern, mit dem Nukleosom als kleinster Einheit. Das Nukleosom besteht aus DNS, die um ein Histon-Oktamer, bestehend aus je zwei Kopien der vier Kernhistone H2A, H2B, H3 and H4, gewickelt ist. Um DNS-basierte Prozesse zu ermöglichen, muss der Zugang zur DNS reguliert werden. Ein Mechanismus dafür ist der Austausch der kanonischen Histone durch eine ihrer Varianten. Bislang wurden fünf Mitglieder der Histon H3 Familie beschrieben: H3.1, H3.2, H3.3, tH3, das nur im männlichen Reproduktionsorgan vorkommt und CENP-A, das an den Zentromeren der Chromosomen zu finden ist. Durch eine Datenbanksuche, konnten wir vor Kurzem im Humangenom zwei neue Histon H3 Variantengene auf Chromosom 5 identifizieren, die jetzt als *H3.X* and *H3.Y* bezeichnet werden. Während meiner Doktorarbeit habe ich ihre Expressionsmuster analysiert, die von ihnen kodierte mRNA, sowie das zugehörige Protein charakterisiert und ihre potentielle(n) Funktion(en) untersucht.

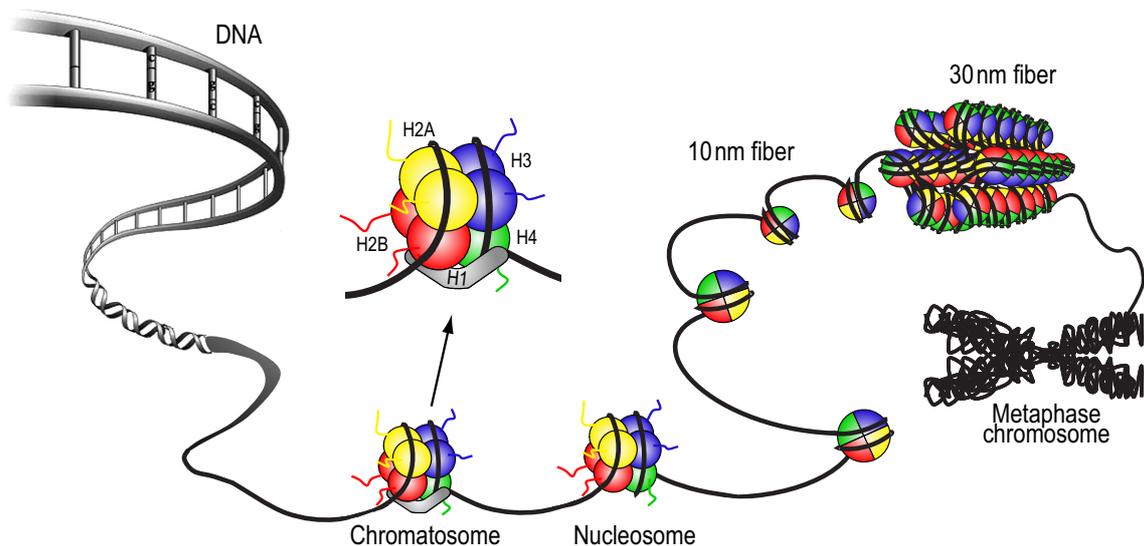

*H3.X* and *H3.Y* sind primaten-spezifische Gene, die, außer im Menschen, auch im Schimpansen und im Rhesusaffen, jedoch nicht in anderen Säugetieren oder niedrigeren Eukaryonten gefunden wurden. *H3.X*- und insbesondere *H3.Y*-mRNA wird in geringen aber dennoch signifikanten Mengen in der humanen Osteosarkoma Zelllinie U2OS und in einigen humanen Knochen-, Brust-, Lungen- und Eierstock-Tumorgewebe, sowie im Hoden und bestimmten Hirnarealen exprimiert. Epitop-markierte *H3.X*- und *H3.Y*-Proteine verhalten sich ähnlich wie H3.1, H3.2 und H3.3 bezüglich ihrer Lokalisierung im Zellkern und ihrem stabilen Einbau ins Chromatin. Im Gegensatz zu H3.1 und H3.3, bilden die neuen H3 Varianten jedoch vorzugsweise heterotypische Nukleosomen. Endogenes *H3.Y*-Protein wird in einer kleinen Anzahl von U2OS-Zellen (<0.1 %) exprimiert, es befindet sich im Zellkern und stellt einen stabilen Bestandteil des Chromatins dar. Die Anzahl *H3.Y*-exprimierender U2OS-Zellen kann durch spezifische Stress-Stimuli erhöht werden, beispielsweise durch Nahrungsmangel gepaart mit hoher Zelldichte. Vergleichbar mit dem Expressionsmuster in U2OS-Zellen, konnten *H3.X* und/oder *H3.Y*-Protein(e) auch in einer kleinen neuronalen Subpopulation im humanen Hippocampus detektiert werden. *H3.Y* beeinflusst die Expression bestimmter Gene, von denen die meisten an der Regulation des Zellzyklus sowie der Struktur des Chromatins beteiligt sind. In Übereinstimmung mit diesem Befund, ist das Wachstum von Zellen mit verminderten Mengen *H3.X* und *H3.Y* beeinträchtigt.

Zusammengenommen zeigen diese Ergebnisse dass *H3.Y* (und vielleicht auch *H3.X*) neue primaten-spezifische Histon H3 Varianten sind, die an der Zellzyklus-Regulation beteiligt sind. Ihre Expression wird durch bestimmte Stress-Stimuli induziert und ihr Vorkommen in Gehirn- und Hodengewebe spricht für eine potentielle Rolle in primaten-spezifischen Hirnfunktionen sowie der Artenbildung.

between H2A-H2B dimers and the (H3-H4)<sub>2</sub> tetramer is mediated by weak 4HBs between the  $\alpha 2$  and  $\alpha 3$  helices of H2B and H4 (Fig. 1.1B) (Luger et al., 1997). To achieve higher levels of compaction, the nucleosome core particle is bound by one molecule of the linker histone H1, forming a chromatosome (Fig. 1.2) and organizing additional 15 to 20 bp of DNA (Simpson, 1978). H1 has a different structure than the core histones, consisting of a conserved globular domain with long N- and C-terminal tails. Its C-terminus is enriched in lysines and strongly interacts with DNA. It is well accepted that H1 binds the nucleosome at the DNA entry/exit site at or near the dyad axis, however, its precise binding site is still controversial (Happel and Doenecke, 2009; Woodcock and Ghosh, 2010). Although more than 80 % of the nucleosomes have H1 bound at a given time, H1 is highly mobile, binding nucleosomes only transiently and translocating from one to the other every few minutes (Bustin et al., 2005; Happel and Doenecke, 2009). The next level of chromatin compaction is the formation of the 30 nm fiber (Fig. 1.2), a conformation which is transcriptionally inactive. Albeit investigated in numerous studies, the structure of this fiber remains elusive. The two major models currently being discussed are a solenoid structure, where the order of the nucleosomes follows their sequence along the DNA, or a zigzag structure, where odd and even numbered nucleosomes build separate stacks (Staynov, 2008). Even less is known about higher order chromatin structures, finally leading to a 10000- to 20000-fold higher DNA compaction in metaphase chromosomes (Fig. 1.2) (Woodcock and Ghosh, 2010).

**Figure 1.2. Chromatin - composition and compaction.**

The basic unit of chromatin is the nucleosome, consisting of DNA, wrapped around an octamer of two copies of each of the four core histones H2A (yellow), H2B (red), H3 (blue) and H4 (green). For further compaction, one molecule of the linker histone H1 (gray) can be bound, resulting in a chromatosome. Nucleosomes with linker DNA constitute the 10 nm fiber, which can be further compacted by stacking of nucleosomes, leading to the 30 nm fiber. Little is known about higher-order chromatin structures finally leading to a condensation of the genetic material to the level of metaphase chromosomes. Image adapted from Qiu, 2006 (modified).

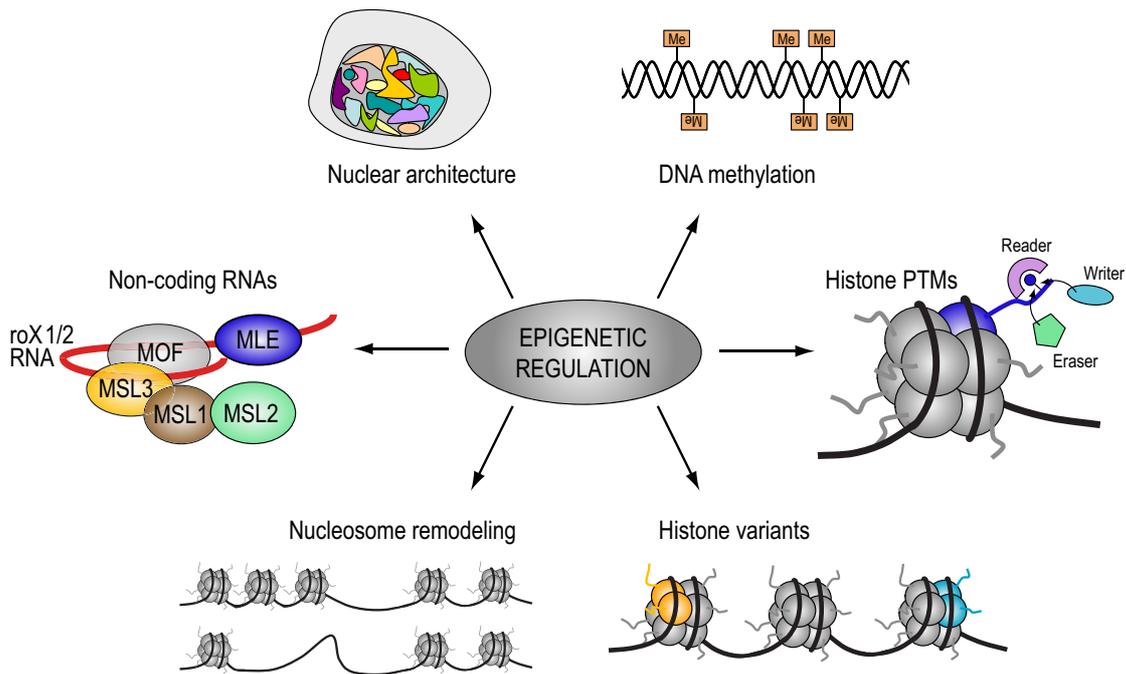

## 1.2 Epigenetic regulation

Except for short stretches of DNA, the genetic information in eukaryotes is associated with histones and packed more or less tightly in higher order structures (see section 1.1). Regions with a more open chromatin structure constitute euchromatin, whereas tightly packed regions are known as constitutive or facultative heterochromatin. Constitutive heterochromatin, such as pericentric heterochromatin, is always silenced. In contrast, facultative heterochromatin is only silenced in certain contexts, for example as part of the inactive X chromosome (Xi) in female mammals. For all DNA-related process, such as transcription or replication, chromatin structure and DNA accessibility have to be regulated. To meet this need, several epigenetic mechanisms have evolved, the major ones being DNA methylation, posttranslational modification (PTM) of histones, incorporation (or replacement) of histone variants, nucleosome-remodeling, non-coding RNAs (ncRNAs) and the position within the nucleus (nuclear architecture) (Fig. 1.3) (Bönisch et al., 2008). The term epigenetics has been coined by Conrad Waddington in 1942 for "the branch of biology which studies the causal interactions between genes and their products, which bring the phenotype into being" (Waddington, 1942; Goldberg et al., 2007). Today, epigenetics is usually defined as heritable changes in genome function that occur without changes in the DNA sequence (Probst et al., 2009). DNA methylation, which denotes the addition of a methyl group to the C-5 position of cytosines, is implicated in long-term silencing. Methylated DNA is therefore often found in heterochromatic regions. During early development, after all methyl marks have been erased, methylation patterns are established *de novo*, marking different sites in the maternal and the paternal genome (imprinting). In somatic mammalian cells, methylation occurs symmetrically at CpG dinucleotides, enabling the maintenance DNA methyltransferase Dnmt1 to copy the marks after replication, thereby maintaining the silenced state of the underlying DNA sequence (Bönisch et al., 2008; Espada and Esteller, 2010).

Histones can be posttranslationally modified, primarily on their N-terminal tails. So far, acetylation, methylation, phosphorylation, ubiquitination, SUMOylation and ADP ribosylation have been described as major marks (Cosgrove, 2007). PTMs are transferred by "writer" and removed by "eraser" enzymes (Fig. 1.3). They act by either changing the charge of a residue, thereby influencing its affinity for the DNA or adjacent nucleosomes, or they establish high-affinity sites for specific "reader" molecules (Fig. 1.3). While acetylation has been generally linked to gene activation, the function of methylation marks depends on the actual residue. Methylated H3 lysine (K) 4 and H3K36, for example, are found in euchromatic regions whereas methylated H3K9, H3K27 and H4K20 constitute heterochromatic marks (Fuchs et al., 2006). Moreover, histones can carry several different PTMs at the same time, estab-

lishing a possible histone-code (Strahl and Allis, 2000; Turner, 2000), which has a different readout than each modification alone. This combinatorial action of histone PTMs also explains how for instance the phosphorylation of H3S10 can promote such different processes as the induction of immediate-early genes (Clayton and Mahadevan, 2003) and the condensation of chromosomes during cell division (Wei et al., 1999; Hendzel et al., 1997). Adding another level of complexity, histones cannot only be modified but also exchanged with one of their replacement variants. These proteins can on the one hand influence the structure and stability of the nucleosome and offer on the other hand alternative modification sites due to sequence differences. The four core histones and the linker histone H1 show variation to different extents. For a more detailed overview see section 1.3.

To move nucleosomes and allow access to nucleosomal DNA, several ATP-dependent nucleosome remodeling complexes have evolved, each containing an ATPase of the SWI/SNF-family. Depending on the ATPase subtype and the factors associated with it, these complexes catalyze the partial or complete disassembly of nucleosomes (histone eviction) or the repositioning of

**Figure 1.3. Epigenetic regulation.**

Schematic overview depicting major epigenetic regulatory processes which act on different levels. DNA is methylated on specific cytosines. Histones, organizing DNA in nucleosomes, can be posttranslationally modified by "writer" enzymes, thereby changing the charge and/or the binding site for specific "reader" molecules. PTMs can also be removed by "eraser" enzymes. In addition, histones can be exchanged by histone variants with different sequences, resulting in a change of structural properties and PTM sites. Accessibility of chromatinized DNA can be regulated by ATP-dependent nucleosome remodeling, for example shifting or evicting nucleosomes. NcRNAs are implicated in diverse processes. Examples are the roX1/2 RNAs in the *Drosophila* dosage compensation complex and Xist RNA, implicated in X chromosome inactivation in mammals. Not only the packaging of DNA is important for DNA-related processes, but also the localization within the nucleus. Histone gene clusters for instance, localize to nuclear Cajal bodies where specific histone mRNA processing factors are concentrated. All of these processes do not act alone but are interconnected. See text for details.

nucleosomes along the DNA (nucleosome sliding) (Fig. 1.3) (Becker and Hörz, 2002; Saha et al., 2006). Nucleosomes, which have histone H1 bound, can also be remodeled, but only by some of the complexes (Maier et al., 2008). It is important to mention that remodelers do not just increase the accessibility of the DNA but can also establish repressive chromatin states (Becker and Hörz, 2002; Saha et al., 2006).

NcRNAs are a diverse class of molecules, differing in size, structure and function. They can influence gene expression levels, either acting post-transcriptionally or directly influencing transcription. One example for the latter is the RNA-induced initiation of transcriptional gene silencing (RITS) complex in *Schizosaccharomyces pombe*, which is targeted to homologous sequences by small ncRNAs and mediates the formation of heterochromatin (Bernstein and Allis, 2005). In addition, long ncRNAs, such as Xist, which is implicated in X chromosome inactivation in female mammals (Bernstein and Allis, 2005), HOTAIR, which silences certain *HOX* genes in humans (Rinn et al., 2007) and roX 1/2, components of the dosage compensation complex in flies, mediating the two-fold activation of the single male X chromosome (Fig. 1.3) (Bernstein and Allis, 2005), have been described. Taking into account that most of the genome is actually transcribed (Gerstein et al., 2007), future studies will certainly reveal more regulatory ncRNAs, maybe also acting by completely different mechanisms.

Within the nucleus, sub-structures can be observed, which lack a demarcating membrane and are instead defined by the presence of a certain set of proteins (e.g. Cajal or PML bodies). Moreover, in interphase cells, chromosomes adopt distinct territories, the position of which seems to be dependent on chromosome size, gene density and morphology. Despite some recent studies showing on the one hand that in human cells localization of genes to the nuclear periphery influences their expression and explaining on the other hand some long-range interactions of specific loci in detail, the general mechanisms how nuclear architecture influences gene expression are still unknown (Schneider and Grosschedl, 2007; Nunez et al., 2009).

Although all of these mechanisms can function independently, in most cases several of them act together to establish and maintain a certain chromatin state (Bönisch et al., 2008). One prominent example illustrating this complexity, is the X inactivation in female mammals, where one X chromosome is silenced through the concerted action of DNA methylation, histone PTMs, histone variants and ncRNAs.

### 1.3 Histone variants

The core histones H2A, H2B, H3 and H4 and the linker histone H1 show variation to a different extent. Since this variation is not only dependent on the protein but also on the species, this overview focuses on mammalian and in particular human histone variants.

Histone variants fall into two groups, canonical histones and replacement variants. The genes encoding canonical histone proteins are intron-free, replication-dependently expressed, organized in multi-copy clusters and their mRNAs have a conserved stem-loop structure at the 3' end instead of a poly(A) tail. This unique 3' structure, together with the stem loop binding protein (SLBP), is responsible for the processing, translation and degradation of canonical histone mRNAs. They thereby ensure high expression levels throughout S-phase, when large amounts of histones are needed for replication, followed by a rapid degradation at the end. Histone gene clusters typically contain multiple copies of each of the genes encoding for the five different histone proteins. A possible reason for this organization is that it allows them to be brought together in a domain enriched in factors required for their expression, the Cajal bodies in mammals. In contrast, replacement variants are encoded by solitary genes (or have only a few copies) outside of histone gene clusters. They usually contain introns, their mRNA is polyadenylated and they are expressed throughout the whole cell cycle (Marzluff et al., 2008).

For H4, no variants have been identified in mammals up to now (Table 1.1 and Fig. 1.4D). The reason for this lack of variation is presumably that H4 interacts with all other histones in the octamer, leaving little room for structural changes (Luger et al., 1997). In the following sections, the four other histone families are introduced and the diverse functions of their members described. For a summary of the data presented about core histone variants, see Table 1.1.

### 1.3.1 H1 variants

The linker histone H1 family shows high variability but the number of H1 variants differs extremely between species. In mammals for example, 11 H1 variants have been identified, while *Drosophila melanogaster* has only one. Focusing on human H1 variants, differences in temporal and spatial expression (Izzo et al., 2008), ability to bind and condense chromatin (Clausell et al., 2009), as well as localization to eu- or heterochromatic areas (Th'ng et al., 2005) have been reported. *H1.1-H1.5* and *H1t* are replication-dependently expressed and part of histone gene clusters whereas genes encoding replacement variants such as H1.0 are found outside of these clusters and are expressed independent of replication (Happel and Doenecke, 2009; Izzo et al., 2008). H1.2-H1.5 are present in all somatic cells with H1.2 and H1.4 being the predominant forms in most of the cells. In contrast, H1.0 is mainly expressed in terminally differentiated cells and H1.1 expression has so far only been reported for certain tissues (Meergans et al., 1997). H1x is currently the least well characterized of the human H1 variants and its expression has only been analyzed in a limited number of cell types (Happel

et al., 2005). The four remaining variants constitute a set of germ cell-specific proteins with H1oo being expressed in oocytes and H1t, H1T2 and HILS1 in testis (Happel and Doenecke, 2009; Izzo et al., 2008). Regarding H1.0-H1.5, it could be shown that they differ in their sub-cellular localization and that this localization is dependent on their C-terminal domain. H1.4, for instance, is associated with heterochromatin in most of the cells, whereas H1.2 and H1.3 are mainly found in euchromatic areas (Th'ng et al., 2005). Using native-like chromatin in form of minichromosomes, Clausell and coworkers analyzed the ability of human somatic H1 variants to condensate chromatin, classifying them as weak (H1.1 and H1.2), intermediate (H1.3) and strong condensers (H1.0, H1.4, H1.5 and H1x) (Clausell et al., 2009). To assess the biological role of individual variants, knockout studies in mice have been conducted. Knockout of one of the H1 variants H1.2, H1.3 and H1.4 alone or together with H1.0 did not show any obvious phenotype. Under these conditions, the remaining subtypes are up-regulated, compensating and maintaining a normal H1/core nucleosome ratio (Sirotkin et al., 1995; Fan et al., 2001). However, careful analysis of these knockout mice revealed specific effects in many cases. For H1.0, for instance, it could be shown that it is essential for the terminal differentiation of dendritic cells (Gabrilovich et al., 2002). Interestingly, triple-null mice, lacking H1.2, H1.3 and H1.4, die by mid-gestation with a broad range of defects. The ratio of H1 to nucleosomes is reduced by 50 % and the spacing between nucleosomes is shortened globally (Fan et al., 2003). In embryonic stem (ES) cells derived from these mice, albeit chromatin structure is changed dramatically, surprisingly the expression of only a small number of genes is affected. Many of these genes are usually regulated by DNA methylation, arguing for a role of (some) H1 variants in the establishment or maintenance of specific DNA methylation patterns (Fan et al., 2005). Depletion of each of the variants H1.0 and H1.2-H1.5 in human breast cancer cells, leads to alterations in a different subset of genes and different effects on cell cycle. Decreased levels of H1.2 induce G1 arrest in T47D and MCF10A breast epithelial cell lines and apoptosis in the breast cancer cell line MCF7. Moreover, depletion of H1.4 causes cell death in T47D cells, providing the first evidence for a crucial role of an H1 subtype for the survival of human cells (Sancho et al., 2008). In line with these results, studies in the last couple of years have revealed specific effects of certain H1 variants in other biological processes. Human 1.2, for example, has been shown to dissociate from chromatin after occurrence of DNA double strand breaks (DSB). It accumulates in the cytoplasm where it triggers the release of cytochrome c from mitochondria, thereby transmitting apoptotic signals from the nucleus (Konishi et al., 2003). Further examples for specific roles of H1 variants in different organisms are summarized in Izzo et al., 2008.

Taken together, these data propose two distinct roles for linker histone variants: On the one hand, H1 variants are redundant in their ability to mediate global chromatin compaction

and to stabilize higher order chromatin structures. In knockout cells, the loss of a particular variant can therefore be compensated by the up-regulation of other H1 subtypes. On the other hand, each variant regulates a subset of specific genes, a role which cannot be compensated by other variant proteins (Izzo et al., 2008).

**Table 1.1. Human core histone variants.**

Distribution over species (Distribution), cell cycle expression profile (Expr.), sub-cellular localization (Localization), functional profile (Function) and specific chaperone (Chaperone) are summarized for all human core histone variants known to date. See text for details. Table, based on Bernstein and Hake (2006) and Talbert and Henikoff (2010), has been amended and updated with recent findings.

	Variant	Distribution	Expr.	Localization	Function	Chaperone
<b>H2A</b>	H2A	Widespread	RD	TG	Genome packaging	NAP1?

ND = not determined, RD = replication dependent, RI = replication independent, TG = throughout genome, Xi = inactive X chromosome, ? = hypothesized, TFBS = transcription factor binding sites. \*)  $\gamma$ -H2A.X (= H2A.XS139ph) localizes to DNA DSBs and a population of small nuclear foci. \*\*) H2.Z is a universal variant but only vertebrates have two genes giving rise to two different H2A.Z proteins.

### 1.3.2 H2A variants

The most variable core histone is H2A, for which four major variants are known to date: H2A.X, H2A.Z, macroH2A and H2A.Bbd (Barr-body deficient). These proteins show - in addition to sequence variations - also different lengths compared to canonical H2A.

The universal variant H2A.X is highly similar to H2A but is distinguished by its conserved C-terminal SQ-motif (Fig. 1.4A). Its unique S139 is phosphorylated at sites of DNA damage (Rogakou et al., 1998, 1999) by the DNA damage signaling kinases ATM (ataxia telangectasia mutated), ATR (ATM- and Rad3-related) and DNA-Pk (DNA-dependent protein kinase)

(Burma et al., 2001; Stiff et al., 2004). The phosphorylated form, termed  $\gamma$ -H2A.X, is present at sites of DSBs during DSB repair, meiotic recombination (Mahadevaiah et al., 2001), apoptotic digestion (Rogakou et al., 2000), V (D) J splicing (Chen et al., 2000), and class switch recombination (Petersen et al., 2001). These data suggest  $\gamma$ -H2A.X to be a universal cellular response to DSBs, functioning in the maintenance of genome stability. Emerging evidence proposes that  $\gamma$ -H2A.X also plays a role outside DSBs, for example in the replication of fac-

**Figure 1.4. Protein sequences of human core histone variants.**

Schematic representation of human core histone variants. Proteins are divided in N-terminal tail and globular domain with C-terminal tail. Human (A) H2A (yellow), (B) H2B (red), (C) H3 (blue) and (D) H4 (green) variants are depicted. Highly divergent protein sequences are visualized by different color shades without highlighting sequence differences. Amino acid differences are indicated when variants differ only in few key residues (for example H3 variants) or when variant-specific amino acids are posttranslationally modified (for example the SQEY-motif in H2A.X). PTM sites are marked as follows: ellipse = phosphorylation, square = methylation, triangle = acetylation, trapezoid = ubiquitination. The macrodomains of macroH2A histones are not drawn to scale. Their triangular shape indicates non-histone-like sequences. MacroH2A1.1 and macroH2A1.2 are splice variants (differentially spliced exon 6), denoted by an internalized white or black triangle in their macrodomain. Note that spH2B, another H2B variant, is not depicted because its protein sequence has not been identified yet. See text for details. Image adapted from Bernstein and Hake, 2006, amended with recent findings.

ultative heterochromatin on the Xi. However, these functions are less well understood and subject of current research (Ismail and Hendzel, 2008).

The second universal H2A variant is H2A.Z, which shows ~60 % sequence identity to canonical H2A. H2A.Z plays a role in such diverse processes as gene activation, chromosome segregation, heterochromatin silencing, and progression through the cell cycle (Zlatanova and Thakar, 2008). Aiming to explain how H2A.Z can fulfill its contrasting functions, several modes of regulation have been identified. In humans, H2A.Z has been found to be enriched in promoter regions up- and downstream of transcription start sites with binding levels matching gene expression (Zlatanova and Thakar, 2008). Furthermore, posttranslational modifications seem to regulate H2A.Z function as H2A.Z acetylation levels are higher in euchromatic compared to heterochromatic regions and mono-ubiquitinated H2A.Z, which is found on the Xi, seems to be important for transcriptional repression (Talbert and Henikoff, 2010). Further variability is observed in vertebrates, where two isoforms, H2A.Z-1 and H2A.Z-2, that differ in three amino acids (Fig. 1.4A), are encoded by two different genes (Coon et al., 2005; Dryhurst et al., 2009; Matsuda et al., 2010). H2A.Z-1 knockout is lethal in mice (Faast et al., 2001) and separate knockdown of both isoforms results in distinct alterations in cell growth and gene expression (Matsuda et al., 2010). Moreover, H2A.Z-1 and H2A.Z-2 are differentially expressed in some tissues and show similar but not identical distributions in chromatin (Dryhurst et al., 2009). Taken together, these data suggest that H2A.Z-1 and H2A.Z-2 have non-redundant functions and differential effects on nucleosome stability and chromatin structure.

In 1992, the first of the macroH2A variants was identified, later named macroH2A1.1. Its N-terminal third is 64 % identical to H2A and its C-terminal part (~30 kDa) constitutes a macrodomain (Pehrson and Fried, 1992). Its isoform macroH2A1.2, differing in a short stretch of amino acids in the non-histone domain, originates from the same gene by alternative splicing (Rasmussen et al., 1999). MacroH2A2, which is 80 % identical to macroH2A1.2, is encoded by a second gene (Fig. 1.4A) (Chadwick and Willard, 2001a). MacroH2A1.2 and macroH2A2 have different nuclear localization patterns but are both enriched on the Xi (Costanzi and Pehrson, 1998, 2001; Chadwick and Willard, 2001a), suggesting a role in X inactivation and, as they are expressed at similar levels also in males (Rasmussen et al., 1999), maybe as general repressors of transcription. However, several studies could show that macroH2A is not necessary for X inactivation, thereby also questioning macroH2A's role as general repressor (Gamble and Kraus, 2010). Two studies, mapping macroH2A localization by ChIP-chip, could recently show association of macroH2A with a large number of autosomal genes. MacroH2A-associated genes are enriched for H3K27me3, a mark for facultative heterochromatin (Buschbeck et al., 2009; Gamble et al., 2010), and consistent with this finding, most of these genes are transcriptionally silent. However, roughly 20 % of macroH2A1-bound

genes are expressed and, surprisingly, macroH2A1 positively affects about 75 % of its target genes (Gamble et al., 2010). In addition to its role in transcriptional regulation, macroH2A also seems to play a role in development as all three variants are differentially expressed in a tissue- and development-dependent manner (Pehrson et al., 1997; Costanzi and Pehrson, 2001). Furthermore, macroH2A may also be implicated in cell proliferation as its association with the Xi is cell cycle dependent and disrupted by the phosphorylation of S137, which is dramatically up-regulated during mitosis (Bernstein et al., 2008). Additionally, macroH2A becomes re-distributed when cells exit the cell cycle (Gamble et al., 2010).

Regarding sequence differences, the most variable H2A variant is the mammalian H2A.Bbd, which is only 48 % identical to H2A. In humans, it is encoded by three intronless genes on the X chromosome giving rise to two proteins that differ in only one amino acid (Fig. 1.4A) (Chadwick and Willard, 2001b). H2A.Bbd lacks the H2A C-terminus containing an acidic patch that directly contacts histone H4 (Luger et al., 1997). None of the PTM-carrying residues in H2A is present in H2A.Bbd, instead, the protein has a stretch of six arginines in its N-terminal tail (Fig. 1.4A). Tagged H2A.Bbd is co-localizing with acetylated histone H4 and excluded from the Xi, suggesting an association with transcriptionally active chromatin (Chadwick and Willard, 2001b). Reconstituted nucleosomes containing H2A.Bbd have a more relaxed conformation (Bao et al., 2004; Gautier et al., 2004; Montel et al., 2007) and organize only 120- 130 bp of DNA (Bao et al., 2004; Doyen et al., 2006). H2A.Bbd has been proposed to constitute an acetylation independent device for the local unfolding of chromatin, thereby promoting transcription (Eirín-López et al., 2008). In addition, H2A.Bbd is involved in spermatogenesis where it probably facilitates the exchange of histones with protamines by destabilizing the nucleosome and is retained at some sites in sperm cells (Ishibashi et al., 2010).

### 1.3.3 H2B variants

In the nucleosome, the H3-H4 tetramer interacts with the H2A-H2B dimer through contacts made by H2B with H4 (Luger et al., 1997). This important structural role of H2B is most likely the cause for the presence of just three human H2B variants which, in addition, are restricted to the male germinal cell lineage (Fig. 1.4B and Table 1.1). Although little is known about all of these variants, maybe the most enigmatic is the human-specific spH2B, which was discovered as part of a telomere-binding complex. spH2B shows higher electrophoretic mobility than canonical H2B, binds telomeric DNA *in vitro* and shows a punctuate localization in sperm nuclei, partially coinciding with telomeric DNA (Gineitis et al., 2000).

The most conserved of the human H2B variants is the testis/sperm-specific variant hTSH2B, an ortholog of the rodent TH2B, which shows 85 % similarity to canonical H2B (van Roijen

et al., 1998; Zalensky et al., 2002). hTSH2B is only expressed in a sub-population of sperm cells (~30%) where it localizes specifically to the basal part of the nucleus, adjacent to the sperm tail attachment point. Distinct foci in cells expressing lower hTSH2B levels, propose a possible association with specific chromatin domains (Singleton et al., 2007; Zalensky et al., 2002). Expression of hTSH2B promotes a more rapid and comprehensive chromatin decondensation, suggesting a potential role in pronuclei formation and the activation of paternal genes following fertilization and during early embryonic development (Singleton et al., 2007). On the molecular level, it could be shown that although hTSH2B has a destabilizing effect on histone octamers, nucleosomes containing this novel variant are structurally and dynamically indistinguishable from their canonical counterpart (Li et al., 2005). The most pronounced sequence differences between somatic H2B and hTSH2B are found at the N-terminus (Zalensky et al., 2002), a region which in H2B is involved in interactions with DNA and important for mitotic and apoptotic condensation of chromosomes (de la Barre et al., 2001; Cheung et al., 2003). Residues, known to be phosphorylated, are missing or re-positioned and novel potential phosphorylation sites have been introduced (Kimmins and Sassone-Corsi, 2005). Interestingly, S14, phosphorylated in H2B by Mst1 kinase during apoptosis (Cheung et al., 2003), is replaced by a phenylalanine in hTSH2B (Fig. 1.4B), raising the question whether hTSH2B has the potential to prevent sperm cells from undergoing apoptosis (Bernstein and Hake, 2006).

In 2004, a primate- and testis-specific H2B variant, termed H2BFWT (H2B family member W, testis-specific), has been identified. The *H2BFWT* gene is located on the X chromosome and encodes a highly divergent H2B variant with only 45% amino acid sequence identity with somatic H2B. Interestingly, the syntenic region on the mouse X chromosome is considerably shorter, suggesting that H2BFWT and its paralogs (three to five genes, clustered tightly on the X chromosome) have either evolved recently in the primate lineage or have been lost in rodents (Churikov et al., 2004). In a nucleosomal context, H2BFWT behaves similar to canonical H2B as shown by equal mobilization and remodeling efficiencies using SWI/SNF on *in vitro* reconstituted chromatin. This can be explained by the fact that H2BFWT sequence mainly differs in the N-terminal tail, whereas the core region, which determines the nucleosome structure, is more conserved. Although it does not influence overall nucleosome structure, the altered N-terminus has an effect on H2BFWT behavior as it leaves the protein unable to recruit chromosome condensation factors and to assist in the assembly of mitotic chromosomes (Boulard et al., 2006). Regarding the function of this novel variant, initial experiments have shown that H2BFWT partially localizes to the interstitial telomeric blocks, suggesting a telomere-associated function (Churikov et al., 2004). More recent results link H2BFWT to male infertility: A single nucleotide polymorphism in the 5' UTR of H2BFWT

has been identified, which severely reduces translation of H2BFWT, causing reduced sperm count and vitality (Lee et al., 2009).

Recently, two novel testis-specific H2B variants (H2BL1 and H2BL2), involved in pericentric heterochromatin reprogramming during mouse spermatogenesis, have been identified. H2BL1 and H2BL2 are not homologous to any of the described human H2B variants, underlining the high diversity of testis-specific histone variants (Govin et al., 2007).

### 1.3.4 H3 variants

In mammals, five histone H3 variants have been described to date: H3.1, H3.2, H3.3, H3.1t (tH3, testis-specific) and CENP-A (centromere-specific). Except for CENP-A, sequence differences are quite subtle among H3 proteins (Fig. 1.4C). H3.1 and H3.2 are distinguished by a single amino acid exchange at position 96, with H3.1 carrying a cysteine and H3.2 a serine. Both are replication-dependently expressed, but H3.1 is only found in mammals, whereas H3.2 is present in all eukaryotes except for budding yeast (Bernstein and Hake, 2006). Due to their high similarity, they are often treated as one protein. However, quantitative mass spectrometry analyses have revealed that expression levels and PTM patterns of these variants vary between different mammalian cell lines and tissues, arguing for distinct protein species (Hake et al., 2006; Garcia et al., 2008). H3.2 is enriched in di- and trimethylated K27, modifications associated with transcriptional silencing and marks of facultative heterochromatin. In contrast, H3.1 shows enrichment in K9 dimethylation, K64 monomethylation and K14 acetylation. K9 dimethylation is found in areas of constitutive heterochromatin (Hake et al., 2006). An interesting hypothesis, aiming to explain the different functions and modes of action of these H3 variants, is the implication of the unique C96 in H3.1 in intermolecular disulfide bonds. In this model, H3.1 promotes higher order chromatin structures and silencing of certain chromatin regions by forming disulfide bonds with neighboring nucleosomes, lamin B receptor (to retain certain loci at the nuclear periphery) or other yet to be identified factors (Hake and Allis, 2006).

The universal H3 variant H3.3 shows four amino acids difference compared to H3.2. It is expressed and incorporated into chromatin throughout the cell cycle and has been found to be enriched in PTMs associated with active transcription (Bernstein and Hake, 2006). In line with these findings, many studies in different organisms have mapped H3.3 to the complete coding region of transcribed genes and to highly enriched foci in promoter regions, establishing its reputation as activating variant. However, H3.3 also marks inactive genes (maybe accounting for a "poised" state of these genes) and genic as well as intergenic regulatory regions (Elsaesser et al., 2010). In addition, H3.3 has been shown to localize to telomeres (Wong

et al., 2009; Goldberg et al., 2010), is implicated in the establishment of heterochromatin in the mouse embryo (Santenard et al., 2010) and found associated with pericentromeric heterochromatin when its unique serine 31 (Fig. 1.4C) is phosphorylated during mitosis (Hake et al., 2005). Taken together, these data suggest that H3.3 does not simply promote gene transcription but rather has very distinct functions which depend largely on its incorporation at specific loci and its interaction partners (see also section 1.3.5).

The mammalian testis-specific H3 variant tH3 differs in four amino acids from H3.1 (Fig. 1.4C) (Witt et al., 1996). Two of these changes (M71 and V111) have recently been identified to cause the significantly lower stability of tH3-containing nucleosomes which may be important for the replacement of histones with protamines during spermatogenesis (Tachiwana et al., 2010). Although tH3 is primarily expressed in testis, low amounts have also been detected in HeLa cells (Andersen et al., 2005), mouse embryos and adult mouse brain and spleen (Govin et al., 2007). The function of this somatic tH3 fraction remains to be determined.

The most divergent of the mammalian H3 variants is CENP-A, which shows only ~60% homology to H3 in its histone-fold domain and has a highly variable N-terminus (Sullivan, 2001). CENP-A localizes to the centromere of eukaryotic chromosomes and is essential for the assembly of the kinetochore, the attachment point of spindle microtubules during cell division. Although it is still unclear what exactly defines centromere position, several lines of evidence now suggest that it is determined by epigenetic marks, maybe the most crucial being the replacement of canonical H3 by CENP-A (Mehta et al., 2010). CENP-A is essential as its knockout in mice is lethal early in development with embryos showing severe mitotic problems, chromatin fragmentation and hypercondensation (Howman et al., 2000). In human cells, where depletion of CENP-A causes cell death accompanied by severe mitotic defects, a complete rescue can be achieved by replacement with histone H3 carrying the centromere-targeting domain (CATD) of CENP-A (Black et al., 2007). The CATD is necessary and sufficient for nucleosome assembly at centromeres and it is responsible for the unique conformational rigidity of CENP-A-containing nucleosomes (Black et al., 2004, 2007). Several studies have shown that nucleosomes containing centromere-specific histone H3 (CenH3) have an unusual structure. In *Drosophila*, for example, they seem to consist of a heterotetramer of H2A, H2B, CenH3 and H4, rather than an octamer. In addition, it has been proposed that centromeric nucleosomes organize DNA in a right-handed wrap (Talbert and Henikoff, 2010). However, the recently solved crystal structure of the CENP-A-H4 tetramer suggests that CENP-A-containing nucleosomes are octameric with conventional left-handed DNA wrapping (Sekulic et al., 2010). In summary, CENP-A seems to be the essential epigenetic factor that marks centromere location by restructuring the nucleosome from within its globular domain, mediated by the CATD.

### 1.3.5 Targeted chromatin incorporation of histone variants

With the growing knowledge about histone variants that partly show very distinct localization patterns, the question arose, how they are targeted and incorporated at such specific chromatin sites. For proteins playing a role in these processes, the term "histone chaperone" has been coined (Koning et al., 2007). In the last 30 years, multiple histone chaperones, implicated in the storage, transport or deposition of a certain variant or a group of histone proteins, have been described (Koning et al., 2007; Eitoku et al., 2008).

The targeted incorporation of H2A-H2B variant dimers is mediated by several different proteins. NAP1 functions as a shuttle for H2A-H2B from the cytoplasm to the nucleus (Loyola and Almouzni, 2004). In addition, it was shown to assemble nucleosomes *in vitro* (Ishimi et al., 1987, 1984) and to interact with H2A-H2B *in vitro* and *in vivo* (Chang et al., 1997; Ishimi et al., 1987; Ito et al., 1996), suggesting it to be a H2A-H2B-specific chaperone. However, biochemical studies indicate that NAP1 preferentially binds H3-H4 when all core histones are present (McBryant et al., 2003; Mazurkiewicz et al., 2006; Eckey et al., 2007), questioning the specificity of this chaperone for the H2A-H2B dimer. In budding yeast, it has been shown that Htz (H2A.Z) is deposited by Chz1 together with the SWR1 complex (Luk et al., 2007; Korber and Hörz, 2004). The conserved CHZ motif conferring this function, is also found in human HIRA-interacting protein 3 (HIRIP3), a factor shown to interact with core histones (Lorain et al., 1998). In addition, p400/Domino and SRCAP, homologs of the SWR1 complex, have been identified which are able to exchange H2A-H2B with H2A.Z-H2B dimers (Gévry et al., 2007; Ruhl et al., 2006). It is tempting to speculate that HIRIP3 constitutes the human H2A.Z-specific chaperone, which together with p400/Domino or SRCAP is responsible for the site-specific incorporation of H2A.Z. H2A.X deposition could be shown to be mediated by the FACT complex. Chromatin incorporation is promoted by phosphorylation of H2A.X, whereas poly-ADP-ribosylation of the FACT subunit Spt16 reduces H2A.X exchange activity (Heo et al., 2008). For the other known H2A variants, macroH2A and H2A.Bbd, so far, no specific chaperone has been identified.

In the last couple of years, chaperones for most of the mammalian H3 variants have been found. H3.1 is deposited by the CAF-1 complex (Tagami et al., 2004) in a DNA-synthesis-coupled manner. Through the interaction with PCNA, CAF-1 is targeted to the replication fork (Shibahara and Stillman, 1999; Krude, 1995) and to sites of damaged DNA in UV-treated cells (Green and Almouzni, 2003; Polo et al., 2006). For H3.2, no specific chaperone has been described so far, but as it differs in only one amino acid from H3.1 (Fig. 1.4C), it seems likely that it is also deposited by CAF-1. For several years, it has been clear that the replication-independent deposition of H3.3 is mediated by HIRA (Tagami et al., 2004). However, several

recent publications have now shown that the picture is much more complex: HIRA is required for the incorporation of H3.3 at active and repressed genes, but it is dispensable for deposition at telomeres and many transcription factor binding sites (Goldberg et al., 2010). Instead, H3.3 incorporation at telomeres and the repression of telomeric RNA is mediated by the novel histone chaperone Daxx together with ATRX (Drané et al., 2010; Lewis et al., 2010; Goldberg et al., 2010; Wong et al., 2010). Moreover, phosphorylated DEK, associating with casein kinase 2, acts as a H3.3 chaperone in flies and humans. In flies, DEK has been shown to be a co-activator of the nuclear ecdysone receptor. Interestingly, in humans the deposition of H3.3 is impaired in acute myeloid leukemia patients carrying a chromosomal translocation fusing DEK to CAN (Sawatsubashi et al., 2010). For the testis-specific variant tH3, nothing is known about its deposition *in vivo*. However, *in vitro*, NAP2, a paralog of NAP1, efficiently incorporates tH3 into nucleosomes (Tachiwana et al., 2008). Only recently, the Holliday junction-recognizing protein (HJURP) has been identified as the chaperone specifically depositing the centromere-specific H3 protein CENP-A (Dunleavy et al., 2009; Foltz et al., 2009). Surprisingly, while centromeric DNA is replicated during S-phase, recruitment of new CENP-A by HJURP in human cells is restricted to a short time window at late telophase/early G1, leaving the cell with only 50 % of the maximal CENP-A nucleosome complement during G2 and mitosis (Jansen et al., 2007; Hemmerich et al., 2008; Dunleavy et al., 2009; Foltz et al., 2009). Whether H3 is incorporated instead or these sites remain unoccupied, is currently unclear, although it is known that H3.1 nucleosomes can be assembled with alpha-satellite DNA and that they can be found interspersed with CENP-A nucleosomes (Blower et al., 2002).

Despite the fact that the precise targeted chromatin incorporation mechanisms are still not known for a lot of histone variants, the so far identified complex processes and multitude of chaperones lead to the speculation that there might be one or several special histone chaperones for the deposition of each variant.

### 1.3.6 Evolution of histone variants

Histones, especially H3 and H4, are among the most conserved proteins in the eukaryotic genome. Nevertheless, a whole range of variants with quite specific functions have evolved. Two different models for the evolution of multigene families have been described: concerted evolution and the birth-and-death model of evolution. In concerted evolution, for example acting on rRNA genes, the members of the gene family are homogenized by interlocus gene recombination or gene conversion. In contrast, evolution by the birth-and-death model assumes, that new genes are created by repeated gene duplication and that some of these genes remain

in the genome for a long time whereas others are deleted or become nonfunctional. This mode of evolution applies for instance to the family of immunoglobulins (Nei and Rooney, 2005). Histone genes have long been thought to evolve through concerted evolution, however, this would mean that synonymous (silent) and nonsynonymous mutations should occur at almost the same frequency in these genes. In several studies, investigating the linker histone H1 (Eirín-López et al., 2004) as well as all four core histone families (Piontkivska et al., 2002; Rooney et al., 2002; González-Romero et al., 2008, 2010), it has now been shown that the frequency of synonymous substitutions is much higher than that of nonsynonymous. This observation speaks for an evolution of histone gene families driven by the birth-and-death mechanism combined with a strong purifying selection on the protein level.

Regarding the diversification into multiple variants, the first idea would certainly be that the respective non-specialized variant constitutes the ancestral form. However, two aspects speak against this hypothesis: First, some of the specialized variants, such as H2A.X and H3.3, are, in contrast to their canonical forms, universally expressed (Table 1.1). Second, it is difficult to imagine that something like the conserved S-Q-E/D- $\Phi$ -motif of H2A.X ( $\Phi$  = hydrophobic residue, Fig. 1.4A) has appeared independently multiple times in evolution. Therefore, it seems likely that these specialized but universal proteins constitute the ancestral histones (Talbert and Henikoff, 2010).

## 1.4 Objective

Over the last 20 years, several novel histone variants of the mammalian H1, H2A and H2B family (e.g. macroH2A (Pehrson and Fried, 1992) or H2BFWT (Churikov et al., 2004)) have been described, but regarding H3, it was thought that with the identification of CENP-A (Palmer et al., 1987) and tH3 (Trostle-Weige et al., 1984) the set of this particular histone family was complete. However, searching the histone database (<http://research.nhgri.nih.gov/histones/>), several putative histone H3 variant genes were listed, opening up the fascinating possibility of a whole range of additional H3 proteins with unique functions. In my PhD thesis I was aiming to characterize the most interesting candidate(s) of this list in terms of (A) expression levels in different cell lines and tissues, (B) sub-cellular localization and (C) biological function.

## 2 Materials and Methods

### 2.1 Materials

#### 2.1.1 Technical devices

Description	Supplier
-20 °C Freezer	Bosch, Liebherr
-80 °C Freezer	GFL
4 °C Fridge	Siemens, Liebherr
37 °C Incubator (bacteria)	Memmert
37 °C Incubator (mammalian cells)	Heraeus
Agarose gel chamber	Repair shop of Adolf-Butenandt-Institute
Autoclave (Varioklav)	H+P
2100 Bioanalyzer	Agilent
Cell counter	Casy Cell Counter, Innovatis
Centrifuges	Heraeus Megafuge 2.0 Haereus Biofuge pico Thermo/Heraeus Pico 17 Thermo Shandon Cytospin 4 Eppendorf Centrifuge 5810R Hettich Rotina 46
Concentrator plus	Eppendorf
Developer machine Curix 60	Agfa
Ettan microLC (HPLC)	Amersham Pharmacia Biotech
Gel documentation system	Peqlab
Hood	CleanAir
HPLC C4 column (250 x 4.6 mm Jupiter 10 µm 300 Å)	Phenomenex
Imaging system	LI-COR
Incubation shaker (Multitron)	Infors
LightCycler <sup>®</sup> 480 II	Roche
LC Ultimate 3000	Dionex
LTQ Orbitrap XL	Thermo
Microscopes	DMIL LED (Leica) Axiovert 200M (Zeiss) LSM 510 META confocal (Zeiss) LSM 710 confocal (Zeiss) personalDV widefield epifluorescence (Applied Precision) UltraVIEW VoX spinning disc (PerkinElmer)

<b>Description</b>	<b>Supplier</b>
Microscopes	OMX DeltaVision prototype (Applied Precision)
Microwave	LG
MilliQ-water	Millipore
Odyssey <sup>®</sup> imaging system	LI-COR
pH-meter	inoLab pH 720
Pipetboy	Integra Biosciences
Pipettes	Gilson
Power supply	BioRad
Proteingel chamber (Novex Mini Cell)	Invitrogen
REPETMAN <sup>®</sup> multistep pipet	Gilson
Rotating wheel	Neolab, VWR
RTCA DP Analyzer	Roche
Scales	Sartorius
Shaker	Roth
Spectrophotometer	Nanodrop ND1000, Peqlab
ThermalCycler 2720	Applied Biosystems
Thermomixer 5436	Eppendorf
Trans Blot <sup>®</sup> SD Semi-dry transfer cell	BioRad
UV Stratalinker 1800	Stratagene
Vortex Genie 2 <sup>®</sup>	Bachofer
Water bath	Memmert

### 2.1.2 Chemicals and consumables

Unless otherwise stated, all common chemicals are purchased in analytical grade from Merck.

<b>Description</b>	<b>Supplier</b>
1.5 ml and 2 ml reaction tubes	Greiner, Sarstedt
15 ml and 50ml tubes	Sarstedt
96-well plates	Peqlab
Acetonitrile	Roth
Agarose SeaKem <sup>®</sup>	ME Biozym
Ampicillin	Roth
Aqua-Poly/Mount	Polysciences
Bacto Agar	BD
Bacto Tryptone	BD
Cling film	Saran
BSA 98%	Sigma
Cellculture plates	Sarstedt
Cellophan	Roth
Combitips plus	Eppendorf
Complete Protease Inhibitor Cocktail Tablets	Roche
Coomassie Brilliant Blue R	Sigma

<b>Description</b>	<b>Supplier</b>
Cover slips	Roth
Cryovials	Roth
DAPI	Invitrogen
Developer	Agfa
DMSO	Sigma
DNA oligonucleotides	Sigma
dNTP mix	NEB
DTT	Roth
Dulbecco's Modified Eagle Medium (DMEM)	Invitrogen (low glucose + GlutaMAX) PAA (high glucose + L-glutamine)
Dynabeads <sup>®</sup> M-280 Sheep anti-Mouse IgG	Invitrogen
ECL <sup>™</sup> Western Blotting Detection Reagents	Amersham
EDTA	Sigma
EGTA	Sigma
Ethidium bromide	Sigma
FCS dialyzed	Sigma
Filter paper	Whatman 3MM Whatman
Filter tips	Sarstedt, Molecular BioProducts
Filter unit Nalgene	0.2 µm filter holes
Fixer	Agfa
FuGENE HD Transfection Reagent	Roche
G418-sulfate (TC)	PAA
Glass pipettes 5 ml and 10 ml	Hirschmann <sup>®</sup>
Glassware	Schott

## 2.3 Cell biological methods

### 2.3.1 Cultivation and manipulation of mammalian cells

#### 2.3.1.1 Cultivation of mammalian cells

All mammalian cell lines used in this work (see Tables 2.8 and 2.9) were kept in their respective media in a 37 °C incubator with a humidified atmosphere of 5 % CO<sub>2</sub>. For details regarding media composition see Tables 2.8 and 2.9.

Cells were split every 2 to 3 days in a ratio between 1:2 and 1:8 depending on the doubling time of the cell line. Suspension cells (Raji): Cell suspension was partially discarded and replaced by fresh medium. Semi-adherent cells (HEK293): Cells were washed from the plate with the medium covering the cells, cell suspension was partially discarded and replaced by fresh medium. Adherent cells (fibroblasts, HeLa, osteosarcoma and neuroblastoma cells): Medium was removed, cells were washed once with sterile PBS and trypsin/EDTA-solution (1:8-diluted in sterile PBS) was added. Detached cells were resuspended in fresh growth medium, cell suspension partially discarded and replaced by fresh medium.

When harvesting cells for further experiments, cells were counted using a Casy cell counter, pelleted by gentle centrifugation (310 g, 10 min) and washed once with PBS.

For storage, cells were resuspended in FCS + 10 % DMSO, transferred to cryo vials and frozen at  $-80^{\circ}\text{C}$ . For long term storage, frozen vials were kept in liquid nitrogen. Cells in culture were replaced every 2 to 3 months. A fresh vial was thawed quickly in a  $37^{\circ}\text{C}$  water bath, cells were pelleted by gentle centrifugation, DMSO containing FCS was removed and cells were cultured as usual.

### 2.3.1.2 Cultivation of U2OS cells under different stress conditions

In order to identify the factor and/or condition that triggers H3.X/Y expression in U2OS cells, different stress treatments were tested.

**Starvation and Overgrowth (SO):**  $1 \cdot 10^6$  cells were seeded in a 10 cm plate with 7 ml medium. Cells were incubated over 8 days without splitting or replacement of medium.

**Overgrowth:** Cells were seeded identical to SO treatment and incubated over 8 days without splitting but with replacement of medium every day.

**Starvation:**  $1.5 \cdot 10^6$  cells were seeded in a 15 cm plate with 12 ml medium. Cells were kept at 40-60 % confluency by splitting, however, old medium was added back to the cells afterwards.

**UV-treatment:** Normally grown cells were treated with  $25000 \mu\text{J}/\text{cm}^2$ ,  $50000 \mu\text{J}/\text{cm}^2$  or  $100000 \mu\text{J}/\text{cm}^2$  UV light using a Stratalinker 1800 followed by 3 h incubation at  $37^{\circ}\text{C}$ .

**Amino acid depletion:** Normally grown cells were incubated for up to 9 h in Krebs-Ringer Bicarbonate Buffer, a medium lacking amino acids.

**Serum depletion:** Normally grown cells were incubated for up to 12 h in DMEM containing 0.1 %, 0.5 %, 1 %, 1.5 %, 2 % or 10 % FCS.

### 2.3.1.3 Establishment of stably transfected human cell lines

Cells were seeded in 6-well plates 24 h prior to transfection to reach a confluency of 80-90 %. 1  $\mu\text{g}$  plasmid DNA was diluted with Opti-MEM to a final volume of 100  $\mu\text{l}$ , 3  $\mu\text{l}$  FuGENE HD reagent were added and the transfection complex was allowed to form over 15 min at room temperature (RT). The complex was added drop-wise to the cells while shaking the plate. After 24 h incubation at  $37^{\circ}\text{C}$ , medium was exchanged by selection medium (DMEM + 10% FCS + 1% P/S + 600  $\mu\text{g}/\text{ml}$  G418-sulfate) to select for stable cell lines. Selection was carried out until cells in non-transfected control wells had died. Stable cell lines were grown in medium supplemented with 400  $\mu\text{g}/\text{ml}$  G418-sulfate.

### 2.3.1.4 mRNA knockdown using small interfering RNAs (siRNAs)

HeLa, HeLa HA-H3.X, HeLa HA-H3.Y and U2OS cells were transfected with siRNAs to specifically reduce H3.X and/or H3.Y mRNA levels (for siRNA sequences see Table A.3). Transfections were performed using Oligofectamine transfection reagent according to the manufacturer's instructions. In brief: Cells were seeded 24 h prior to transfection for a confluency of 30%. Plate size was chosen depending on the number of cells needed for subsequent analyses (for volumes used for different plates, see table below). For solution (A), Oligofectamine was diluted in Opti-MEM. For solution (B), siRNA stock solution (100  $\mu$ M in 1x Universal Buffer) was first diluted 1:5 in sterile MilliQ-water and then further 1:8.5 in Opti-MEM. After 5 min incubation at RT, solutions (A) and (B) were mixed and the transfection complex was allowed to form over another 20 min period at RT. Cells were washed twice with sterile PBS, growth medium was replaced by DMEM (Invitrogen) not supplemented with serum or antibiotics and the transfection complex was added. After 5 h incubation at 37 °C, DMEM (Invitrogen) supplemented with 30% FCS but without antibiotics was added. The next day, medium was replaced with normal growth medium (Invitrogen). Cells were harvested 4 days after transfection. As U2OS cells are difficult to transfect, a double-knockdown on two consecutive days was performed. Cells were harvested 4 days after the first transfection.

Plate	Solution (A)		Solution (B)		Medium	
	Oligofectamine	Opti-MEM	siRNA(20 $\mu$ M)	Opti-MEM	DMEM	DMEM + 30% FCS
<b>12-well</b>	3 $\mu$ l	7 $\mu$ l	5 $\mu$ l	85 $\mu$ l	400 $\mu$ l	250 $\mu$ l
<b>6-well</b>	4 $\mu$ l	11 $\mu$ l	10 $\mu$ l	75 $\mu$ l	800 $\mu$ l	500 $\mu$ l
<b>10 cm</b>	20 $\mu$ l	55 $\mu$ l	50 $\mu$ l	375 $\mu$ l	5 ml	2.5 ml

### 2.3.2 Proliferation analysis of adherent human cells

Proliferation capacity of adherent human cells was analyzed using two different methods: **CASY Counter:**  $2 \cdot 10^5$  cells were seeded in 6-well plates (3 wells per cell line and condition) and either transfected with siRNAs the following day or used directly for analysis of proliferation capacity. Cells were trypsinized and counted every day using the CASY Counter, cell number was adjusted to keep a confluency of 50-70% and mean of cell count in 3 wells was plotted.

**RTCA DP Analyzer equipped with 16-well E-plates:** Baseline was set using 100  $\mu$ l medium (Invitrogen) per well, 4500 cells in 50  $\mu$ l medium were added (4 wells for each cell line and experimental condition) and measurement was started after 30 min incubation at RT during which cells sink to the bottom of the well and start to adhere. Impedance was measured every 15 min over 96 h, providing quantitative information about the biological status of the

cells, including cell number, viability, and morphology. Growth medium was replaced every day. If siRNA-treated cells were analyzed, cells were seeded one day after the last siRNA transfection.

### 2.3.3 Antibody generation and specificity testing

The antibody against H3.X and H3.Y ( $\alpha$ H3.X/Y) was generated by our collaborator Elisabeth Kremmer using a peptide spanning amino acids 9 to 20 of histone H3.X and H3.Y (KATAWQAPRKLP, Peptide Specialty Laboratories GmbH). The peptide was coupled to BSA and ovalbumin (OVA), respectively, and rats were immunized subcutaneously and intraperitoneally with a mixture of 50  $\mu$ g peptide-OVA, 5 nmol CPG oligonucleotide (Tib Molbiol), 500  $\mu$ l PBS and 500  $\mu$ l *incomplete Freund's* adjuvant. Six weeks later, a boost without adjuvant was given. Fusion was performed according to standard procedures (Köhler and Milstein, 1975). Supernatants were tested by differential enzyme-linked immunosorbent assay (ELISA) with the histone peptide and an irrelevant peptide, both coupled to BSA. Monoclonal antibodies reacting specifically with the peptide were further analysed in Western blot and immunofluorescence (IF) microscopy.  $\alpha$ H3.X/Y clone 8H6-2111 of rat IgG2a subclass was deployed in this study.

$\alpha$ H3.X/Y specificity was analyzed by peptide competition assay with subsequent IF analysis (see section 2.3.4). Prior addition to the cells, the antibody (diluted in blocking solution) was incubated for 4 h at 4 °C with the following peptides (1  $\mu$ g/ml): biotin-coupled H3.3 unmodified (aa 22-41) and H3.X/Y unmodified (aa 9-20). Samples were analyzed on an Axiovert 200M microscope.

### 2.3.4 Immunofluorescence (IF) microscopy

Adherent mammalian cells were grown and stained on 12 mm cover slips in 24-well plates. In brief, cells were washed with PBS, fixed for 15 min in 1 % formaldehyde-PBS, permeabilized in PBS-T (PBS + 0.1 % Triton X-100) and blocked for 20 min in PBS-T + 1 % BSA. Samples were incubated stepwise with primary and secondary antibody (diluted in blocking solution) for 30 min with three consecutive 5 min PBS-T washes. For details about antibodies and dilutions see sections 2.1.4.1 and 2.1.4.2. DNA was stained for 5 min with 10 ng/ml 4',6-diamidino-2-phenylindole (DAPI) in PBS and mounted with ProLong Antifade Kit. Samples were analyzed using an Axiovert 200M microscope.

To determine percentage of cells with general nuclear  $\alpha$ H3.X/Y staining, positive cells were

counted and representative pictures of the sample, showing the cell density on the cover slip, were taken. Percentage of positive cells was calculated by dividing the number of positive cells by the average cell number per picture multiplied with the number of pictures per cover slip.

For analysis on a LSM 510 META confocal microscope, DNA was counter stained using To-Pro3 and samples were mounted using Vectashield mounting medium.

Samples for 3D-SIM analysis were prepared on precision cover glass #1.5 ( $0.170\pm 0.005$  mm thick; Roth) and embedded in Vectashield mounting medium. Sample preparation and analysis on an OMX DeltaVision prototype was performed by our collaborator Lothar Schermelleh (Advanced Cell Imaging Unit, LMU Munich).

### **2.3.5 Metaphase chromosome spreads**

Metaphase chromosome spreads of adherent human cells were generated as previously described (Hake et al., 2005). In short, cells were arrested in mitosis by a 15-16 h treatment with nocodazole (transfected HeLa cells: 200 ng/ml; U2OS cells: 1  $\mu$ g/ml), harvested by mitotic shake-off, lysed by incubation in RBS buffer and spread on microscope slides by centrifugation in a Shandon Cytospin 4. Cells were fixed in 2% formaldehyde in PBS and washed with KCM-Tween (1xKCM + 0.1% Tween 20). Chromosomes were extracted with KCM-Tween + 0.1% Triton X-100, washed with KCM-Tween and KCM-Tween-BSA (KCM-Tween + 0.25% BSA), blocked in KCM-Tween + 2.5% BSA and incubated with primary antibody in blocking solution overnight (ON) at 4°C. After washing with KCM-Tween-BSA, chromosomes were incubated with secondary antibody in blocking solution for 1-2 h at RT and washed with KCM-Tween and PBS + 0.1% Tween 20. DNA was stained with 10 ng/ml DAPI for 5 min, samples were washed with PBS and mounted with Vectashield mounting medium. Except for washes, microscope slides were incubated in an opaque wet chamber. Analysis was carried out with a personalDV widefield epifluorescence microscope followed by a deconvolution procedure.

### **2.3.6 Fluorescence recovery after photobleaching (FRAP)**

FRAP analyses were performed by our collaborator Lothar Schermelleh (Advanced Cell Imaging Unit, LMU Munich). HeLa Kyoto cells were transiently transfected with GFP-tagged histone H3 constructs (see section 2.1.5). After 24 h, cells were seeded in Lab-Tek chamber slides and incubated several hours or ON before performing FRAP experiments. FRAP rates

were determined using an UltraVIEW VoX spinning disc microscope with integrated FRAP PhotoKinesis accessory assembled to an Axio Observer D1 inverted stand (Zeiss). The microscope's heated environmental chamber was set to 37°C and 5% CO<sub>2</sub> perfusion. Several square bleach regions with a size of 5 x 5 μm were positioned on selected cell nuclei within the field of view. Photobleaching was performed using two iterations with the Acousto Optic Tunable Filter (AOTF) of the 488 nm and the 514 nm laser line set to 100% transmission. To determine long-term recovery kinetics, 3D image stacks of 8 μm height and a z-distance between image planes of 1 μm were recorded with an initial speed of 1 f/min for the first 10 frames, followed by intervals of 10 min. Using ImageJ, raw data were corrected for lateral and rotational movements of the nucleus, differences in background and gain or loss of total fluorescence during postbleach acquisition, potentially caused by newly synthesized GFP-histones, bleaching-by-acquisition and flux of residual fluorescence from above and below the recorded optical plane. To correct for cell-to-cell differences in bleaching depth, the data were normalized to zero by subtracting the first postbleach value from all mean fluorescence values.

### **2.3.7 Immunohistochemistry (IH) microscopy**

Commercially available human tissue sections were stained in an opaque wet chamber at RT unless stated otherwise. Frozen sections were thawed and blocked in PBS + 0.5% Triton X-100 + 0.5% BSA for 30 min. Samples were incubated with primary antibody in blocking solution ON at 4°C followed by three 10 min PBS-washes. Incubation with secondary antibody in blocking solution was carried out for 2h followed by three 10 min PBS-washes. To enhance H3.X/Y signals, biotin-coupled secondary αrat antibody was used followed by a 2h incubation with streptavidin coupled to an Alexa 555 fluorophor diluted in PBS. DNA was counter stained for 5 min with 1 μg/ml DAPI in PBS and samples were mounted using Aqua-Poly/Mount. Analysis was carried out on a LSM 710 confocal microscope.

## **2.4 Molecular biological methods**

### **2.4.1 Agarose gel electrophoresis**

DNA fragments were separated using 1% agarose gels prepared with TBE buffer. To visualize DNA fragments, ethidium bromide was added to the gel at a final concentration of 0.5 μg/ml.

### 2.4.2 RNA extraction of mammalian cells

Total RNA from  $1-2 \cdot 10^6$  cells was extracted using the RNeasy Kit following the manufacturer's instructions, including removal of genomic DNA contaminations. RNA concentration and purity was determined using a Nanodrop ND1000 spectrophotometer, RNA was stored at  $-80^\circ\text{C}$ .

### 2.4.3 RNA expression profiling

Microarray hybridization was performed by Dietmar Martin and Kerstin Maier of the Gene Center Affymetrix Microarray Platform (Cramer Laboratory, LMU Munich). Bioinformatical analysis was carried out by Tobias Straub (Becker Laboratory, LMU Munich). Concentration and quality of total RNA preparations (see section 2.4.2) were evaluated using the RNA 6000 Nano Kit and the 2100 Bioanalyzer. 100 ng of RNA were further purified with the RNeasy MinElute Cleanup Kit and RNA amplification, labeling and hybridization to Human Gene 1.0 ST Arrays were performed according to the manufacturer's instructions. Raw microarray data were processed in R/Bioconductor as follows: gene-based expression values were calculated using the Robust Multichip Average (RMA) method as part of the 'oligo' package. For downstream analyses, genes with a log<sub>2</sub> expression value of at least 4 in at least one of the treatment conditions were used. Differential expression estimation was based on a moderated t statistic ('limma' package) with subsequent calculation of the local false discovery rate (lfr, 'locfdr' package). Genes were classified as responders by a lfr cutoff of 0.2. Gene ontology enrichment analysis was performed using a hypergeometric distribution test and subsequent Bonferroni correction as supplied by the GOHyperGALL script ([http://faculty.ucr.edu/~tgirke/Documents/R\\_BioCond/My\\_R\\_Scripts/GOHyperGAll.txt](http://faculty.ucr.edu/~tgirke/Documents/R_BioCond/My_R_Scripts/GOHyperGAll.txt)). Term redundancy was reduced by applying the GOHyperGAll.Simplify function with a p-value cutoff of 0.001. The microarray data for siRNA transfected U2OS cells has been deposited at GEO ([www.ncbi.nlm.nih.gov/geo](http://www.ncbi.nlm.nih.gov/geo)) under the accession number GSE22415.

### 2.4.4 cDNA synthesis

cDNA was first synthesized using the ProtoScript First Strand cDNA Synthesis Kit and later the ProtoScript M-MuLV Taq RT-PCR Kit due to discontinuation of the first product. cDNA was transcribed from 1  $\mu\text{g}$  of total RNA (see section 2.4.2) per reaction, following the instructions given in the protocol using random primers. Samples without reverse transcriptase (no

RevT) were processed in parallel to control for genomic DNA contamination. PCR amplification of a GAPDH-mRNA fragment with Taq polymerase and subsequent analysis on an agarose gel was taken as a readout for successful cDNA synthesis (for primer sequences see Table A.1).

#### 2.4.5 Quantification of mRNA levels with quantitative PCR (qPCR)

mRNA levels of genes of interest were quantified relative to mRNA levels of stably expressed reference genes with qPCR using a LightCycler 480 II equipped with a 384-well block. Primer pairs were designed using Primer3 software (Rozen and Skaletsky, 2000), qPCR primers are listed in Table A.1. Samples were analyzed in technical triplicates for each primer pair with a total volume of 15  $\mu$ l per well. For each reaction 0.75  $\mu$ l cDNA (see section 2.4.4) were diluted to 5  $\mu$ l with PCR-grade water and distributed to different wells using a multistep pipet and 0.1 ml combitips. In a second step 7.5  $\mu$ l LightCycler 480 SYBR Green I Master mix (2x) were mixed with primers and PCR-grade water to a volume of 10  $\mu$ l with each primer in a concentration of 0.44  $\mu$ M. SYBR/primer mix was distributed to different wells using a multistep pipet and 0.2 ml combitips. Plate was sealed with adhesive foil, centrifuged for 2 min at 3000 g and qPCR was performed with temperature profile summarized below. Experiments were analyzed using the advanced relative quantification tool of LightCycler 480 SW 1.5 software, factoring in differences in primer efficiency (see below) and calculating mRNA levels relative to a combination of two reference genes (*HPRT1* and *HMBS*). Samples with no RevT cDNA (see section 2.4.4) were used to quantify background levels caused by genomic DNA contamination.

Primer pairs were tested for specificity and efficiency by using non template controls, melting curves and dilution series of cDNA. To calculate primer efficiencies and determine primer specific detection threshold, a dilution series of cDNA, generated from a mix of HeLa HA-H3.X and -H3.Y cells, was used. Standard curves were analyzed using the advanced absolute quantification tool of LightCycler 480 SW 1.5 software.

	Pre-Incubation	5 min	95 °C
		10 s	95 °C
45x	Amplification	10 s	60 °C
		10 s	72 °C
		5 s	95 °C
	Melting Curve	1 min	65 °C
		2.5 °C/min	97 °C

#### 2.4.6 Cloning of mammalian H3 variants

Histone H3 variants were amplified from human cDNA (see section 2.4.4) using gene specific primers flanked by restriction endonuclease recognition sites (for primer sequences see Table A.2) and Phusion DNA polymerase. PCR-products were subcloned with EcoRV in pT7Blue-3 vector, leading to a disruption of the *LacZ* gene, thereby enabling selection of positive clones over blue/white screening. Subcloning reaction was transformed in chemically competent *E. coli* (XL1 Blue or DH5 $\alpha$ ) with a heat shock of 45 s at 42 °C. After 1 h incubation in LB medium at 37 °C, cells were plated on LB agar plates containing the respective antibiotic (ampicillin 100  $\mu$ g/ml or kanamycin 10  $\mu$ g/ml). Plasmid DNA was isolated using a miniprep kit. H3 variant cDNA was excised with the respective restriction endonucleases, fragments were gel purified using a gel extraction kit and ligated with the vector backbone which has been cut and purified in the same way. Ligation reaction was transformed in chemically competent XL1 Blue or DH5 $\alpha$  as described above. Cloning success was verified by sequencing (Eurofins MWG Operon) of isolated and purified plasmids.

#### 2.4.7 Site directed mutagenesis of H3.Y

To perform RNAi rescue experiments, siRNA target regions in H3.Y (as part of pIRES-neo3 HA) were mutated without changing the amino acid sequence. Mutagenesis was performed using Pfu DNA polymerase, following the manual for the Stratagene (Agilent) site-directed mutagenesis kit. Briefly, pIRESneo3 HA-H3.Y was amplified using primers carrying the desired mutation (see Table A.2), template plasmid was digested with DpnI and PCR-reaction was transformed in chemically competent *E. coli*. Plasmid DNA was isolated with a miniprep kit, sequenced and used to establish stable cell lines (see section 2.3.1.3).

#### 2.4.8 Expression of human histone proteins in *E. coli*

*E. coli* expression strain BL21-CodonPlus (DE3)-RIL was transformed with pET-21a(+) H3.X and H3.Y plasmids as described in section 2.4.6. Transformed *E. coli* were grown in LB medium supplemented with kanamycin (10  $\mu$ g/ml) and chloramphenicol (17  $\mu$ g/ml). Expression was induced in an exponentially growing culture for 3 h at 37 °C by adding IPTG to a final concentration of 0.1 mM. Cells were harvested and boiled for 10 min at 95 °C in 1x Laemmli loading buffer. Cell debris was removed by centrifugation and supernatant was used for Western blot analysis.

## 2.5 Biochemical methods

### 2.5.1 Histone extraction from mammalian cells

Histones were acid extracted as previously described (Shechter et al., 2007). In short, nuclei were isolated using hypotonic lysis buffer and extracted with 0.4 M sulfuric acid. Histones were precipitated with 100 % trichloroacetic acid and resuspended in water.

### 2.5.2 Reversed phase-high performance liquid chromatography (RP-HPLC) of mammalian histones

Acid extracted histones (see section 2.5.1) from U2OS, HEK293 and NIH3T3 were separated on an Ettan microLC over a C4 column (250 x 4.6 mm Jupiter 10  $\mu$ m 300 Å) using a linear gradient from 35 % to 53 % solvent B with a flow of 1.0 ml/min over 30 min. Fractions of 200  $\mu$ l were collected, vacuum dried and stored at -20 °C. Fractions containing H3.X and/or H3.Y protein were identified using Western blotting (see section 2.5.8) and analyzed using mass spectrometry (see section 2.5.3).

### 2.5.3 Mass spectrometrical analysis of HPLC-purified mammalian histones

Mass spectrometrical analysis was performed by our collaborator Lars Israel (LMU Munich, Protein Analysis Unit). In brief, RP-HPLC fractions containing H3.X and/or H3.Y (see section 2.5.2) were resolved in 0.1 M ammonium bicarbonate and treated with propionic anhydride to convert free amino groups of lysine residues to propionic amides, thereby preventing digestion after lysines. Proteolytic digestion with sequencing grade trypsin (Promega) was carried out ON at 37 °C and samples were directly loaded onto a nano-ESI-LC-MS/MS for protein identification. The resulting data were analyzed via Mascot software using a home-made database containing the diverse H3 sequences. Fragment spectra were also interpreted manually.

### 2.5.4 Mononucleosome immunoprecipitation (IP)

Mononucleosome IP was performed by Clemens Bönisch, PhD student in the Hake group. Mononucleosomes were generated, with some changes, as previously described (Wysocka et al., 2001). All centrifugation steps prior to Micrococcal Nuclease (MNase) treatment were performed at 3200 g at 4 °C. Briefly, aliquots of  $2 \cdot 10^7$  cells were lysed in buffer A + 0.1 % NP-40,

washed with buffer A and incubated in buffer B. Mononucleosomes were generated by digestion of chromatin with 0.25 U MNase for 15 min at 37 °C in buffer A + 1 mM CaCl<sub>2</sub> and stopped by addition of EGTA (final concentration 2 mM). Un-digested material was removed by centrifugation (20000 g for 20 min), supernatants of five MNase digests were combined and salt concentration was adjusted to 150 mM KCl. Monoclonal mouse  $\alpha$ HA was immobilized on magnetic beads (sheep  $\alpha$ mouse IgG) and IP was performed ON. Beads were washed four times with buffer C and bound mononucleosomes were eluted with 100 mM glycine (pH 2.8). One part of these beads was used to isolate DNA with phenol/chloroform extraction using MaXtract High Density columns followed by sodium acetate/ethanol precipitation. DNA size and quality was evaluated using the DNA 1000 kit with the 2100 Bioanalyzer. From the rest of the beads, bound proteins were eluted by boiling in SDS sample buffer and subsequently analyzed by Western blotting using Licor detection (see section 2.5.8) and silver staining (see section 2.5.7).

### **2.5.5 SDS polyacrylamide gel electrophoresis (SDS-PAGE)**

Proteins were separated using 15 % separating polyacrylamide gels covered by stacking gels using disposable cassettes and 10-, 12- or 15-well combs. Gels were run at 100 V until prestained size marker (peqGOLD Protein Marker IV or V) started to separate. Run was continued at 180 V until loading dye reached end of the gel. Subsequently, gels were stained with Coomassie Blue (see section 2.5.6) or silver nitrate (see section 2.5.7) or used for Western blotting (see section 2.5.8).

### **2.5.6 Coomassie staining of polyacrylamide gels**

Polyacrylamide gels (see section 2.5.5) were incubated for 1 h in Coomassie staining solution, followed by incubation in Coomassie destaining solution until background staining was reduced enough for protein bands to become visible.

### **2.5.7 Silver staining of polyacrylamide gels**

Polyacrylamide gels (see section 2.5.5) were fixed in 40 % ethanol (v/v) + 10 % glacial acid (v/v) ON or used directly after Coomassie staining (see section 2.5.6). Gels were washed in 50 % methanol and water for 10 min, respectively, followed by a 1 min incubation in 0.02 % sodium thiosulfate (w/v) and two 1 min washing steps in water. To stain protein bands,

gels were incubated in 0.1 % silver nitrate (w/v) for 20 min, rinsed twice with water (1 min each) and developed in 0.04 % formaldehyde (v/v) in 2 % sodium carbonate (w/v) with vigorous shaking. To terminate development when protein bands become visible, formaldehyde / sodium carbonate solution was discarded and replaced by 1 % acetic acid.

### 2.5.8 Western blotting

Polyacrylamide gels were blotted on PVDF (ECL detection) or nitrocellulose (Licor detection) membranes using a semi-dry blotting machine. Gel and membrane were equilibrated for 10 min in transfer buffer (PVDF membrane was activated in methanol for 30 s prior to equilibration) and blot was assembled by stacking two 3 mm Whatman papers soaked in transfer buffer, membrane, gel, and two more soaked 3 mm Whatman papers. Air bubbles were removed and proteins were transferred to the membrane over 1 h with 200 mA. Membrane was stained with Ponceau S solution and scanned to monitor protein loading. Membrane was blocked for 1 h in TBS + 0.1 % Tween 20 (TBS-T) + 5 % milk powder (TBS-T milk, ECL detection) or TBS + 5 % milk powder (Licor detection) and incubated ON at 4 °C with primary antibody diluted in TBS-T milk (for dilutions see section 2.1.4.1). Membrane was washed three times with TBS-T, incubated for 1 h at RT (Licor detection: light protected) with secondary antibody diluted in TBS-T milk (for dilutions see section 2.1.4.2) and washed again three times with TBS-T. Membrane was either covered with ECL detection reagent, followed by film exposure and development or scanned with the Licor machine.

## 2.6 Bioinformatics

### 2.6.1 Phylogenetic analysis of histone variants

The phylogenetic tree depicted in Fig. 3.2 was generated using coding nucleotide sequences of different histone variants from human (Hs), chimpanzee (Pt) and macaque (Mm). Sequences were aligned using ClustalW Alignment (MacVector 10.0.2) and evolutionary relationships were determined using the neighborjoining tree-building method based on Kimura 2-parameter with Gamma correction off.

Changes in program parameters and/or inclusion of 3' UTRs as well as analysis of 3' UTRs alone led to virtually the same result. The only difference was that H3.X and H3.Y were either closer to H3.3A or H3.3B.

### 2.6.2 *In silico* modeling of novel histone variants

To generate homology models for H3.X and H3.Y proteins, the I-TASSER server (Zhang, 2008) was used. It provides a combination of threading, assembly and refinement to generate 3D-models. As template, the server automatically chose for both novel variants chain A (histone H3.2) of pdb-file 1kx5. This structure resembles a nucleosome consisting of 147 bp of *Homo sapiens* DNA wrapped around *Xenopus laevis* histones (Davey et al., 2002). The model for H3.X had a C-score of 0.07, the model for H3.Y a C-score of 1.50. In both cases, C-score for the second best model was considerably lower. Data-sets of the models were downloaded and visualized using Swiss-Pdb-Viewer and PyMOL.

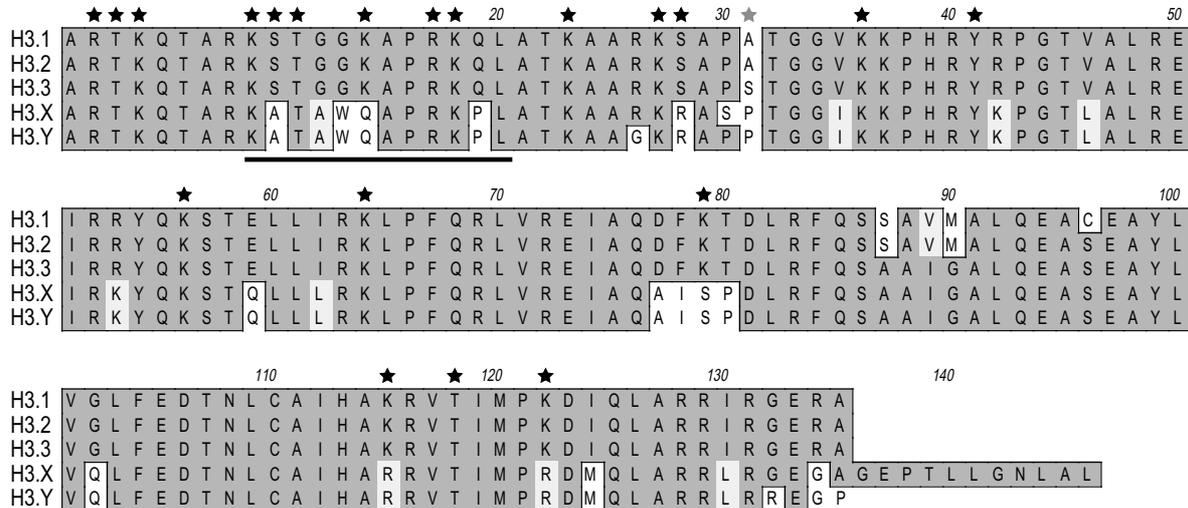

## 3 Results

### 3.1 Identification of novel histone H3 variant genes

Searching the NCBI database with the nucleotide sequence of human histone *H3.1f* (HIST1H3I; NM\_003533), two putative histone H3 variant genes have been found, now termed *H3.X* (LOC340096) and *H3.Y* (LOC391769) (Fig. A.1, Appendix). Both genes were initially annotated as pseudogenes, are located on human chromosome 5 (5p15.1) and do not contain introns. Their sequence around the translation initiation start site matches the consensus for vertebrates (GCCGCCACCAUGGCG) (Kozak, 1991; Nakagawa et al., 2008), and depending on the search program used (polyadq or PolyA\_SVM program), *H3.X* and *H3.Y* 3'-genomic sequences are predicted to include a conserved poly(A) site (Cheng et al., 2006; Tabaska and Zhang, 1999).

*H3.X* and *H3.Y* genes are predicted to encode for highly similar proteins of 146 and 135 amino acids, respectively, with only four amino acids difference in their overlapping region (89.7% identity) (Fig. 3.1). *H3.X* has an additional unusual C-terminal tail with no sequence homology to other proteins. Both putative proteins display interesting sequence differences compared to H3.1, H3.2 and H3.3, thereby generating potential new PTM sites or eliminating amino acids known to be posttranslationally modified. One example is the replacement of serine 10 and 28, phosphorylated during mitosis (Hendzel et al., 1997) and immediate-early gene induction (Clayton and Mahadevan, 2003), by alanine and arginine, respectively. In addition to these single amino acid changes, also complete stretches appear to be altered. The most prominently changed regions include the sequence surrounding lysine 14, usually acetylated and found in actively transcribed genes (Yan and Boyd, 2006), and the region around lysine 79, which is found to be methylated in transcriptionally active regions (Im et al., 2003) and upon DNA damage (Huyen et al., 2004) (Fig. 3.1). The sequence from amino acid 87 to 90 is important for the chaperone-dependent chromatin incorporation of histone variants (Ahmad and Henikoff, 2002). CAF-1 deposits H3.1, whereas HIRA and the Daxx-ATR complex catalyze the incorporation of H3.3 (Tagami et al., 2004; Drané et al., 2010; Lewis et al., 2010). *H3.X* and *H3.Y* amino acids in this region are identical to H3.3 (Fig. 3.1), leading

to the hypothesis that these putative novel variants might be incorporated by HIRA and/or Daxx-ATRAX in a replication-independent manner.

**Figure 3.1. Amino acid sequence alignment of human histone H3 variants.**

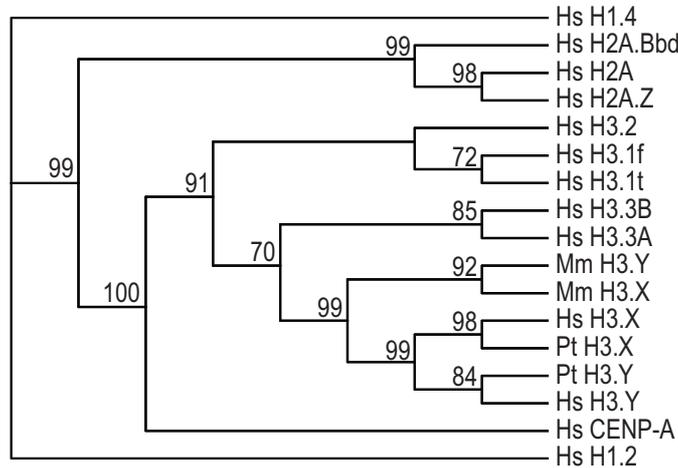

Protein sequences of known human histone variants H3.1, H3.2 and H3.3 are aligned with those of novel histone variants H3.X and H3.Y. Sequence similarity is encoded by background color: identical aa = dark gray, similar aa = light gray, different aa = white. Black stars indicate described PTMs on known H3 variants, gray star indicates H3.3 variant specific PTM. Black bar marks peptide sequence used for generation of  $\alpha$ H3.X/Y antibody.

To shed light on the evolutionary origin of these novel variants, further database searches with H3.X and H3.Y protein sequences were performed, leading to the identification of highly similar genes in the chimpanzee (*Pan troglodytes*: LOC471464 (*H3.X*) and LOC471473 (*H3.Y*)) and the macaque (*Macaca mulatta*: LOC718189 (*H3.X*) and LOC718280 (*H3.Y*)) but not in any other mammalian genome. Predicted H3.X and H3.Y protein sequences of different primates are almost identical with only few single amino acid changes (Fig. A.2, Appendix). The most striking difference is the premature stop codon in the macaque H3.X, resulting in a truncated protein with the size of H3.Y. Interestingly, following nucleotides would code for the unique H3.X C-terminus.

*H3.X* and *H3.Y* genes are located on different chromosomes in the primates analyzed (*Pan troglodytes*: chromosome 5, *Macaca mulatta*: chromosome 6), but the region containing both loci is in all cases flanked by the *CDH18* and the *BASP1* gene. These two genes can also be found on one chromosome in the mouse and rat genome, however, the distance between them is much shorter. Together, these data give rise to the hypothesis that *H3.X* and *H3.Y* loci originate from gene duplications in evolutionary younger terms and constitute primate-specific histone variants. To determine which gene was the origin of this duplication, the phylogenetic tree for the coding nucleotide sequences of human, chimpanzee and macaque *H3.X* and *H3.Y*

together with a variety of other human histone variants was calculated (Fig. 3.2). Clearly visible in this analysis, *H3.X* and *H3.Y* most likely originate from a gene duplication of one of the *H3.3* genes. However, whether the source was *H3.3A* or *H3.3B* cannot be answered with certainty as depending on the sequence used for generating the tree (including or excluding 3'UTR, coding or non-coding sequences), *H3.X* and *H3.Y* appear to be closer to the one or the other (data not shown). In contrast to the human and chimpanzee sequences, macaque *H3.X* and *H3.Y* sequences are more similar to each other than to the respective gene in other species, which might be due to the premature stop-codon in the macaque *H3.X* sequence (Fig. 3.2 and Fig. A.2, Appendix).

In summary, two novel histone H3 variant genes could be identified, termed *H3.X* and *H3.Y*, which seem to be specific for the primate lineage.

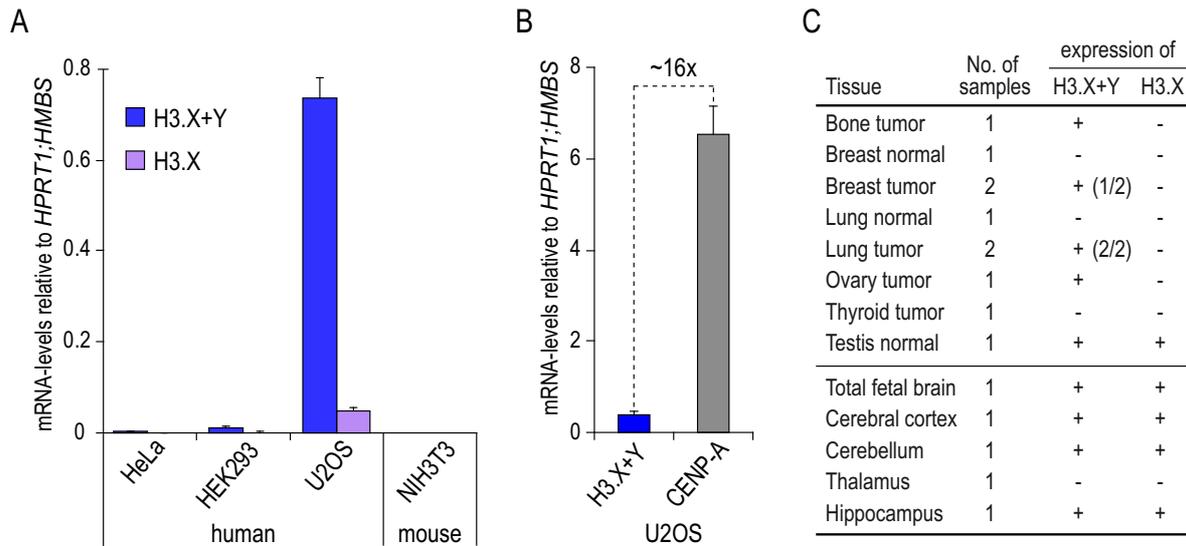

**Figure 3.2. Phylogenetic tree of H3.X and H3.Y from different species.**

Comparison of coding nucleotide sequences of H3.X and H3.Y from different primates with other human histone variants, reveals greater similarity of both variants to H3.3 than to any other variant. Hs = *Homo sapiens*, Pt = *Pan troglodytes*, Mm = *Macaca mulatta*; numbers indicate bootstrap probabilities.

### 3.2 Endogenous *H3.X* and *H3.Y* expression in human cell lines and tissues

To assess if *H3.X* and *H3.Y* are pseudogenes or indeed novel H3 variants, the first step was to analyze their mRNA expression levels in different human cell lines by quantitative PCR (qPCR). One primer pair detecting both variants and one primer pair specifically targeting the unique 3' sequence of H3.X was chosen because of the high sequence similarity between *H3.X* and *H3.Y* (Fig. A.1, Appendix). Both variants are transcribed at low levels in the human osteosarcoma cell line U2OS (Fig. 3.3A). Minimal amounts of H3.Y could be detected

in HEK293 cells, whereas no expression was observed in HeLa cells. As negative control, mouse NIH3T3 cells were used, showing no expression of H3.X or H3.Y (Fig. 3.3A). In U2OS cells, H3.Y is stronger expressed than H3.X but absolute expression levels are still very low, namely  $\sim 16$ -fold lower than CENP-A (Fig. 3.3B). These data suggest that *H3.X* and *H3.Y* genes are transcribed in some human cell lines, albeit at low total levels.

**Figure 3.3. H3.X/Y mRNA levels in different cell lines and human tissues.**

(A) qPCR analysis of endogenous H3.X/Y levels with cDNA from different human and mouse cell lines shows expression of H3.Y and to a lesser extent H3.X in U2OS cells. Primer pairs amplifying H3.X and H3.Y (H3.X+Y, blue) or H3.X alone (purple) were used, levels are depicted relative to HPRT1 and HMBS. Error bars represent SEM of two independent biological experiments. Mouse NIH3T3 cells were used as negative control showing no H3.X/Y expression. (B) qPCR comparison of endogenous H3.X/Y and CENP-A levels with cDNA from U2OS cells, reveals approximately 16-fold higher expression of the latter. Primer pairs amplifying H3.X and H3.Y (H3.X+Y, blue) or CENP-A (gray) were used, levels are depicted relative to HPRT1 and HMBS. Error bars represent SEM of two independent biological experiments. (C) cDNA prepared from commercially available total RNA from different normal and malignant human tissues was analyzed by qPCR for H3.X/Y expression. Tissues positive for H3.X+Y- and H3.X-expression are marked with a "+", numbers of positive samples are indicated in brackets. Controls generated without reverse transcription were used to assess amplification threshold.

Encouraged by the finding that *H3.X* and *H3.Y* are expressed in U2OS cells, the next step was to analyze primary cells as part of human tissues by qPCR. The initial idea was to take malignant tissues as U2OS cells are derived from a moderately differentiated sarcoma of the tibia. In addition, normal tissues for comparison and samples from different brain regions as well as testis were chosen because of the primate-specific appearance of H3.X and H3.Y. H3.X/Y levels were quantified with cDNA, synthesized using commercially available total RNA from the tissues listed (Fig. 3.3C). Interestingly, low but significant expression of H3.X/Y mRNA could be detected in some bone, breast, lung and ovary tumors. In RNA from human brain areas and testis, H3.X/Y expression was observed in all samples except

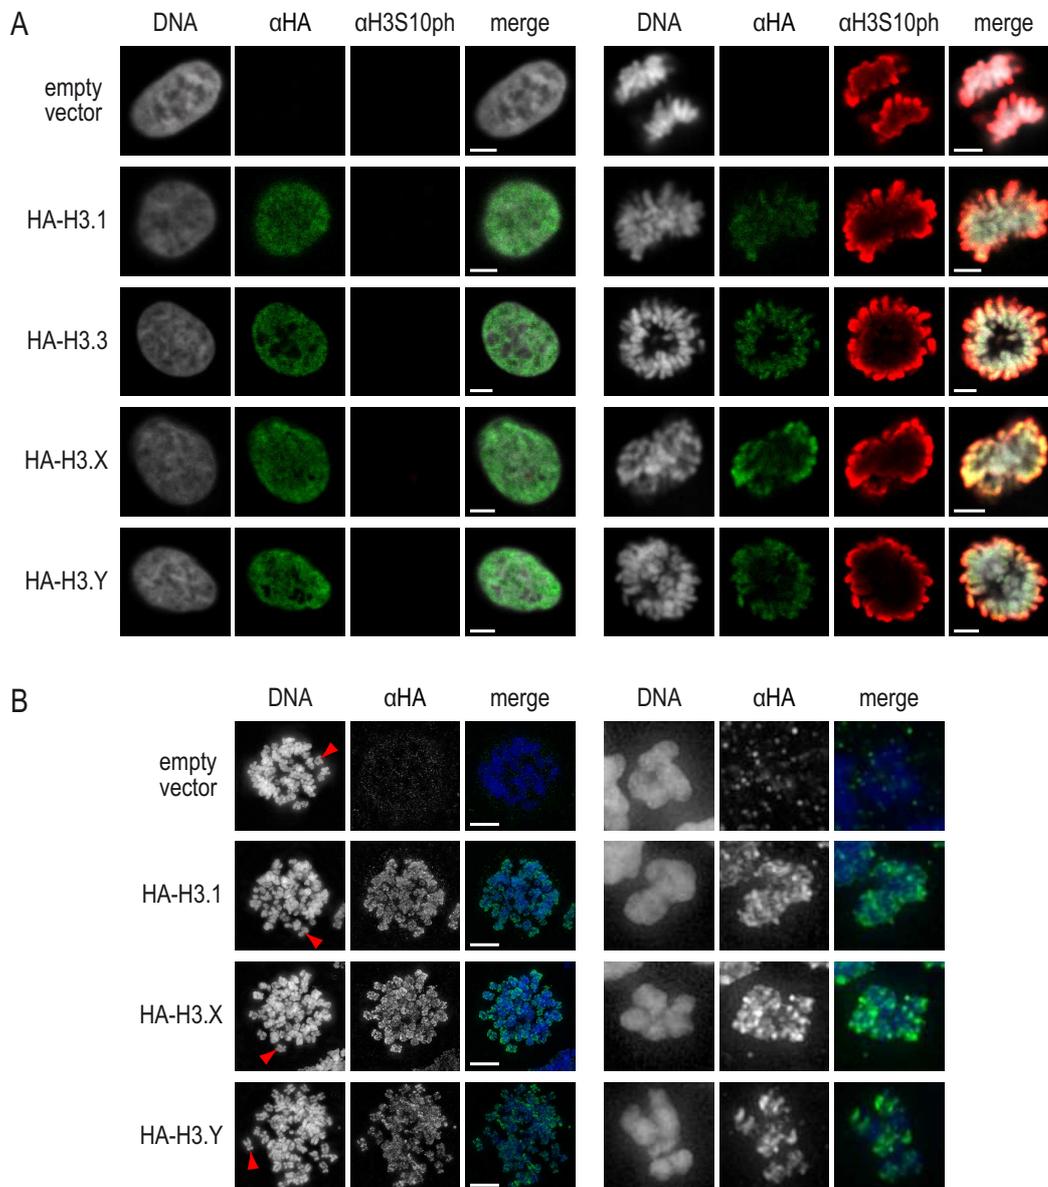

for the thalamus. In contrast to all other tissues tested, also H3.X mRNA was present in these brain and testis samples (Fig. 3.3C). In conclusion, mRNAs of novel primate-specific H3 variants H3.X and H3.Y are not only present in human cell lines, but are also in primary cells from different human organs.

### 3.3 Localization, nucleosome structure and chromatin incorporation of novel tagged H3 variants

To gain insight into the structural features and *in vivo* behavior of H3.X and H3.Y proteins, the coding sequences of H3.X and H3.Y were cloned from human cDNA and HeLa cells, constitutively expressing these with an N-terminal HA-tag, were established. For comparison, HeLa cells, constitutively expressing HA-tagged versions of H3.1, H3.2 and H3.3 (here referred to as "known H3 variants") were used. Confocal imaging of these cells shows solely nuclear localization of all histone H3 variants (Fig. 3.4A). Detection of HA signals in mitotic cells, co-localizing with mitotic chromosomes, points towards chromatin incorporation of all tagged H3 variants analyzed. To further address this point, the same cell lines were used to prepare metaphase chromosome spreads. Immunofluorescence (IF) microscopic analysis of  $\alpha$ HA and DAPI stained spreads shows stable chromatin association of all tagged H3 variants and a distinct localization pattern of individual variants (Fig. 3.4B).

Since H3.X and H3.Y seem to behave like the known H3 variants regarding their localization and chromatin association, we were wondering if the sequence differences between novel and known H3 variants have any influence on protein structure, finally leading to an altered nucleosome structure and stability. In collaboration with Rainer Merkl from the University of Regensburg, homology models based on the crystal structure of *Xenopus laevis* H3.2 (Davey et al., 2002) have been calculated. Overlays of predicted H3.X and H3.Y structures with H3.2 crystal structure show no major changes in secondary or tertiary structure elements (Fig. 3.5A). Interestingly, the extra C-terminus of H3.X is proposed to fold into an additional  $\alpha$ -helix. Exchange of both H3.2 chains in the crystal structure of the nucleosome by H3.X or H3.Y homology models does not result in any sterical clashes with the other histone chains. Surprisingly, the additional  $\alpha$ -helix of the H3.X protein would fit perfectly in the free space in the middle of the nucleosome, close to the acidic patch of H2A (Fig. 3.5B).

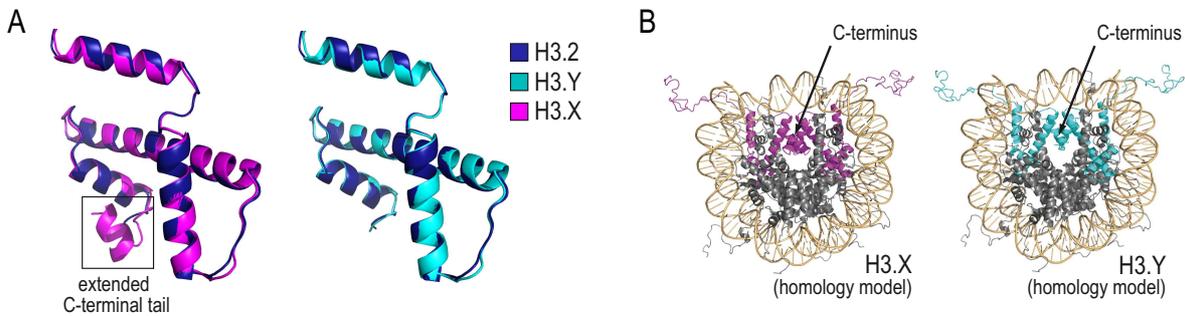

In order to distinguish, whether tagged H3.X and H3.Y are only associated with chromatin or constitute stable core nucleosomal components, the protein composition of mononucleosomes in HeLa cells, expressing HA-tagged H3 variants, was analyzed. Clemens Bönisch, another PhD student in the Hake group, digested isolated chromatin with micrococcal nuclease to

**Figure 3.4. Sub-cellular localization of HA-tagged histone H3 variants.**

(A) HA-tagged histone H3 variants localize exclusively to the nucleus in stably transfected HeLa cells as determined by confocal imaging of interphase cells (left). In mitotic cells, marked by  $\alpha$ H3S10ph staining, HA-tagged histones are associated with condensed chromatin. Cells were co-stained with TO-PRO3 (DNA, gray, left),  $\alpha$ HA (green, middle left) and  $\alpha$ H3S10ph (red, middle right). Overlay is shown on the right (merge). Scale bar equals 5  $\mu$ m. (B) Metaphase chromosome spreads of stably transfected HeLa cells show that all HA-tagged histone H3 variants are incorporated into chromatin. Depicted are projections of deconvolved widefield images of chromosomes co-stained with DAPI (DNA, blue, left) and  $\alpha$ HA (green, middle). Overlay is shown on the right (merge). Blow-ups of single chromosomes, indicated by red arrowheads, are depicted on the right panel. Scale bar equals 10  $\mu$ m.

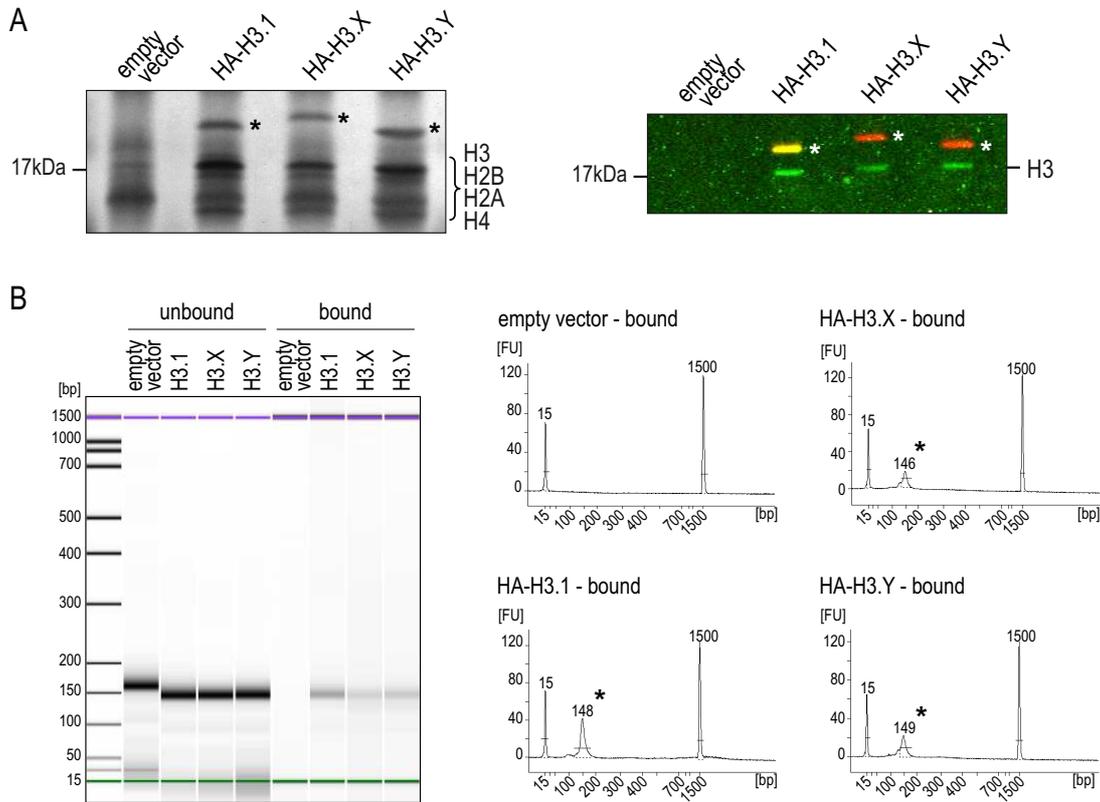

mononucleosomes and immunoprecipitated these using  $\alpha$ HA antibody. Silver staining of a 15% SDS-gel with bound proteins showed successful precipitation of all four core histones (Fig. 3.6A, left). Western blotting of an identical gel, probed with  $\alpha$ H3 and  $\alpha$ H3.X/Y antibodies, revealed the presence of endogenous known H3 variant proteins in all samples except for the negative control (Fig. 3.6A, right), suggesting the presence of novel and known variants in the same nucleosome. 2100 Bioanalyzer analysis of bound DNA gave a single signal, corresponding in its size to mononucleosomal DNA ( $\sim$ 146 bp), thereby verifying digestion to mononucleosomes (Fig. 3.6B). Taken together, these data show that HA-H3.X and -H3.Y constitute core nucleosomal components and are, in contrast to H3.1 and H3.3 (Tagami et al., 2004), able to form heterotypic nucleosomes with known H3 variants.

**Figure 3.5. *In silico* homology models of H3.X and H3.Y protein structure.**

(A) Overlays of H3.2 crystal structure (blue) with H3.X (purple, left) or H3.Y (cyan, right) *in silico* homology models. Predicted tertiary structures of both novel variants are almost identical to H3.2. Extended C-terminal tail of H3.X is proposed to fold into an additional  $\alpha$ -helix (boxed area). (B) Both H3.2 molecules in the crystal structure of the nucleosome are replaced by H3.X (purple, left) or H3.Y (cyan, right) homology models. The additional  $\alpha$ -helix of the H3.X protein is predicted to fold into the free space in the middle of the nucleosome, close to the acidic patch of H2A.

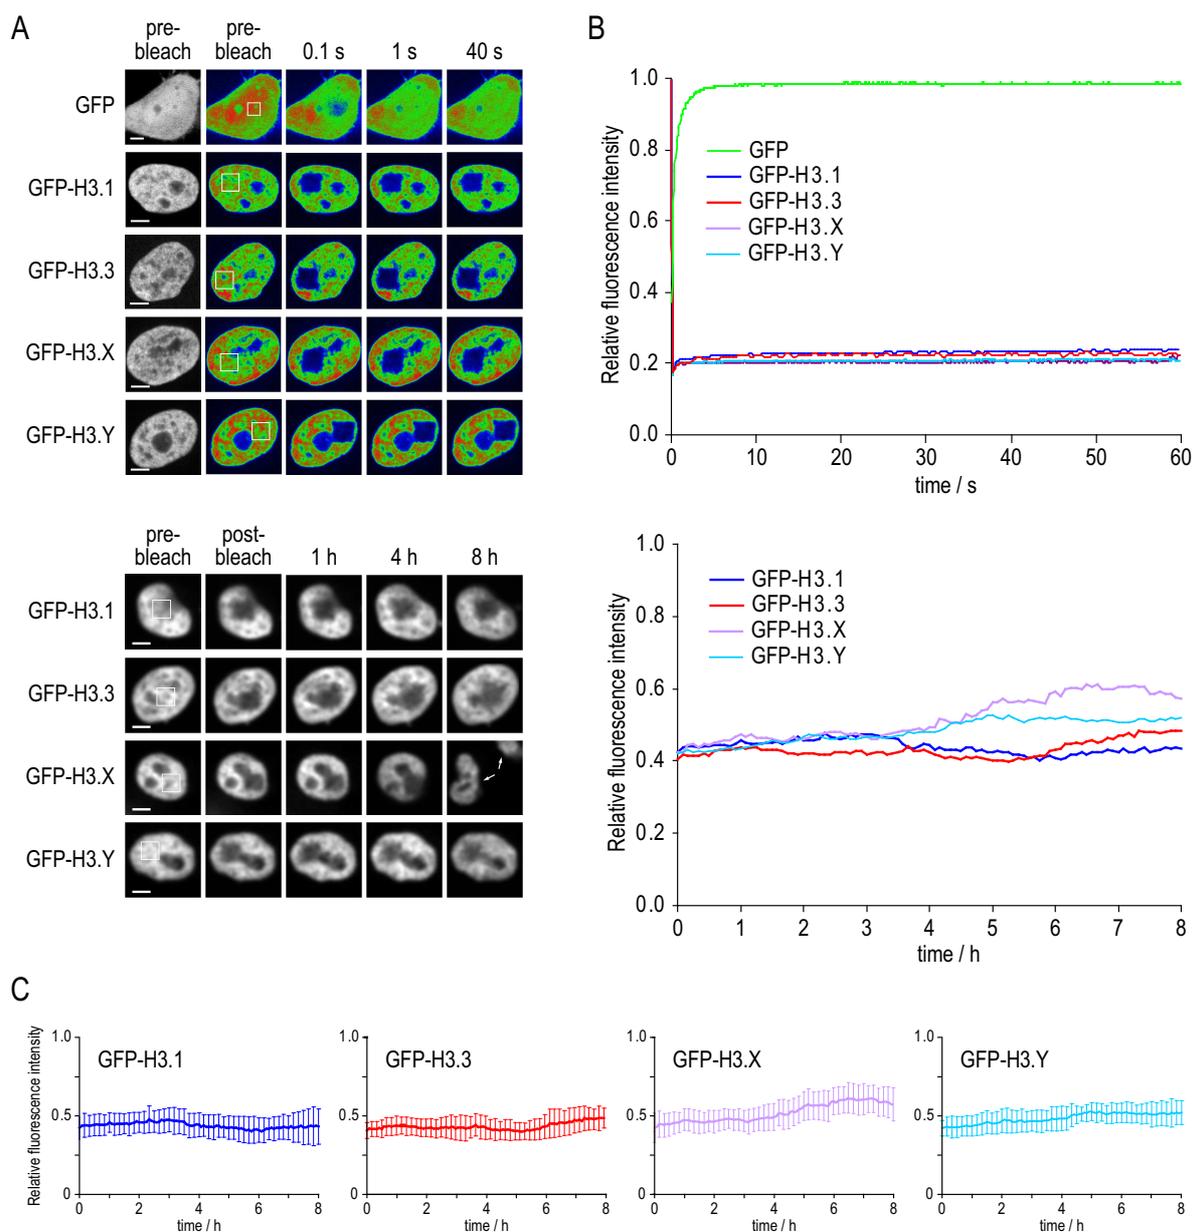

Next we wanted to analyze the *in vivo* stability of nucleosomes containing different H3 variants. These experiments were performed by our collaboration partner Lothar Schermelleh from the LMU Munich and his group. Novel and known H3 variants were cloned with an N-terminal GFP-tag under a constitutively active promoter and transiently transfected into HeLa Kyoto cells. These cells were chosen because of their slow cell motility. In a small area of the nucleus, the fluorescence signal was bleached, followed by a measurement of fluorescence recovery after photobleaching (FRAP) rates. All H3 variants show virtually no recovery of the fluorescence signal, even after 8 h, arguing for highly stable chromatin components. In contrast, GFP alone recovers within seconds (Fig. 3.7A,B). Quantification of long-term FRAP rates (Fig. 3.7B, bottom) indicates some minor differences between H3 variants, however, these differences are within the dynamic range of the method as illustrated by long-term FRAP curves including error bars (Fig. 3.7C).

**Figure 3.6. Composition of H3.X and H3.Y containing nucleosomes.**

Chromatin of HeLa cells, constitutively expressing HA-tagged H3 variants, was digested to mononucleosomes and used for IP with  $\alpha$ HA antibody coupled to magnetic beads. (A) Precipitated material was separated with 15% SDS-PAGE. Gels were either silver stained (left) or immunoblotted with subsequent Licor analysis (right) using  $\alpha$ HA (red) and  $\alpha$ H3 (green) antibodies. All HA-tagged variants (marked with asterisks) were part of a nucleosome as successful precipitation and presence of all core histones indicate. H3.X and H3.Y form heterotypic nucleosomes with other H3 variants, shown by H3 signal in Western blotting (right). (B) DNA of bound and unbound mononucleosomes was isolated and evaluated using the 2100 Bioanalyzer. Gel picture shows successful digestion and precipitation of DNA (left). Marker bands are depicted in purple and green. Size analysis of precipitated DNA verifies digestion to mononucleosomes. Asterisks indicate signal of bound DNA, numbers indicate DNA size in bp (right).

In conclusion, tagged novel variants localize to the nucleus in interphase and mitotic cells, are incorporated into chromatin and show very slow exchange mobility kinetics. Their behavior as well as their proposed tertiary structure is highly similar to the known H3 variants, the major difference being that HA-H3.X and -H3.Y are also able to form heterotypic nucleosomes.

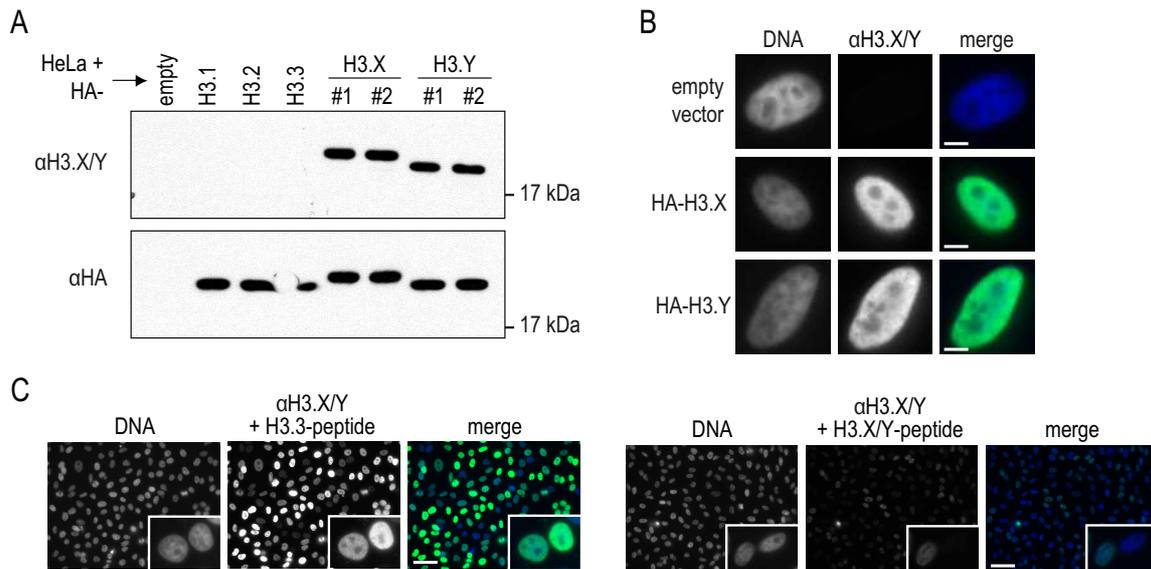

**Figure 3.7. Exchange mobility behavior of GFP-tagged H3 variants.**

HeLa Kyoto cells were transiently transfected with GFP-tagged H3 variants or GFP alone. GFP fluorescence was bleached in a small area of the nucleus and recovery of fluorescence signal was monitored over 1 min or 8 h by spinning disk microscopy. (A) Snapshots of one representative cell per construct at several time points before and after bleaching are depicted. Short-term FRAP analysis shows recovery of GFP signal within seconds (top), whereas GFP-tagged H3 variants do not show any recovery of the fluorescence signal over 8 h (bottom). Bleached area is indicated by a white box. Arrows indicate daughter cells after mitosis. Scale bar equals 5  $\mu\text{m}$ . (B) Quantitification of recovery rates after photobleaching. Mean curves of 10-20 cells are shown for short-term FRAP analysis (top). Error bars are omitted for clarity (standard deviation  $\pm 0.02$ ). For long-term FRAP series (bottom), mean curves of 13-25 cells are plotted. (C) Depicted are mean curves of long-term FRAP experiments including error bars which represent the respective standard deviation: GFP-H3.1 (n=13), GFP-H3.3 (n=15), GFP-H3.X (n=18) and GFP-H3.Y (n=25). All GFP-tagged H3 variants show almost no recovery, indicating stable chromatin incorporation. Subtle differences are within the dynamic range of the measurement and not statistically significant.

### 3.4 Expression and sub-nuclear localization of endogenous H3.X/Y proteins

Having analyzed endogenous H3.X and H3.Y mRNA expression and characteristics of tagged novel H3 proteins, the next step was to examine endogenous H3.X and H3.Y protein expression. Therefore, we developed an H3.X/Y-specific monoclonal rat antibody together with our collaborator Elisabeth Kremmer from the Helmholtz-Center in Munich. The antibody is directed against amino acids (aa) 9-20 of H3.X and H3.Y (for peptide sequence see black line in Fig. 3.1). Antibody specificity was tested in various assays using HeLa cells stably expressing HA-tagged H3 variants.  $\alpha$ H3.X/Y recognizes acid extracted HA-H3.X and -H3.Y proteins but none of the other histone variants in Western blot (Fig. 3.8A), IF microscopy (Fig. 3.8B) and FACS analysis (data not shown). Epitope-specificity was further determined by peptide competition experiments.  $\alpha$ H3.X/Y antibody was incubated with the original peptide used for antibody generation or an unrelated H3.3 peptide prior to use for IF staining.  $\alpha$ H3.X/Y specifically interacted with the H3.X/Y peptide, which prevented the binding of tagged H3.X

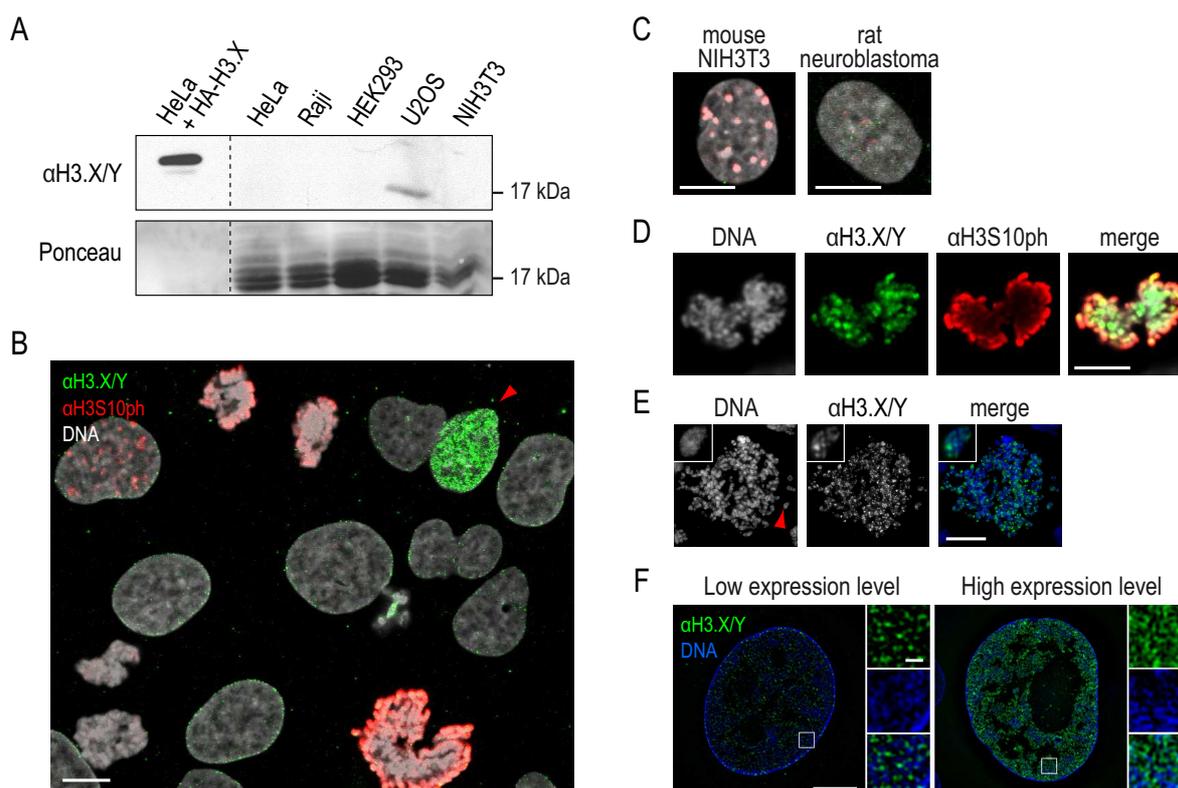

**Figure 3.8. Evaluation of  $\alpha$ H3.X/Y antibody specificity.**

(A) Western blot analysis of acid extracted histones of HeLa cells, stably transfected with HA-tagged H3 variants.  $\alpha$ H3.X/Y antibody recognizes specifically H3.X and H3.Y but none of the other H3 variants (top). Numbers indicate independently selected HeLa cell populations. Incubation with  $\alpha$ HA antibody reveals presence and equal loading of all tagged variants (bottom). Note that all variants migrate slower than endogenous H3 (17 kDa) because of the HA-tag. H3.X migrates even more slowly because of its extra C-terminus. (B) IF microscopy images of HeLa cells stably transfected with empty vector, HA-H3.X or HA-H3.Y, co-stained with DAPI (DNA, blue, left) and  $\alpha$ H3.X/Y (green, middle), shows nuclear localization of tagged H3.X and H3.Y protein. Merged pictures are depicted on the right, scale bar equals 5  $\mu$ m. (C) Peptide competition assay to evaluate epitope-specificity of  $\alpha$ H3.X/Y antibody. HeLa HA-H3.X cells were co-stained with DAPI (DNA, blue, left) and  $\alpha$ H3.X/Y (green, middle) pre-incubated with an H3.3 (aa 22-41) peptide (top) or H3.X/Y (aa 9-20) peptide (bottom). HA-H3.X signal is lost in a H3.X/Y-sequence specific manner. Overlay is depicted on the right (merge). Insets show blow-ups of two representative cells. Scale bar equals 50  $\mu$ m.

in the cell, leading to a loss of fluorescence signal. No binding of  $\alpha$ H3.X/Y to the H3.3 peptide occurred, thereby giving a strong signal for HA-H3.X (Fig. 3.8C).

With this highly specific tool, acid extracted histones from several human cell lines were analyzed for their content of endogenous H3.X/Y protein. Mouse NIH3T3 cells served as negative and HeLa HA-H3.X cells as positive control. Western blot analysis of these histones using  $\alpha$ H3.X/Y antibody, revealed a faint band at 17 kDa for U2OS histones but not for

**Figure 3.9. Endogenous H3.X/Y expression and sub-nuclear localization.**

(A) Western blot analysis of acid extracted histones from different cell lines with  $\alpha$ H3.X/Y antibody reveals a faint band for U2OS cells at 17 kDa but not for any other cell line (top). HeLa HA-H3.X cells were used as positive, mouse NIH3T3 cells as negative control. Membrane was stained with Ponceau S to check protein loading (bottom). Dotted lines indicate that intervening lanes have been spliced out. (B) Confocal imaging of U2OS cells co-stained with  $\alpha$ H3.X/Y (green), H3S10ph (mitosis-specific, red) and TO-PRO3 (DNA, gray) shows a distinct pattern of H3.X/Y staining associated with the nuclear envelope in all inter- and prophase cells, as well as a general nuclear staining in very few cells (marked by a red arrowhead). Scale bar equals 10  $\mu$ m. (C) Confocal imaging of mouse NIH3T3 and rat neuroblastoma cells co-stained with  $\alpha$ H3.X/Y (green), H3S10ph (red) and TO-PRO3 (DNA, gray), used as negative control, shows no H3.X/Y staining. Scale bar equals 10  $\mu$ m. (D) Confocal imaging of a mitotic U2OS cell co-stained with TO-PRO3 (DNA, gray, left),  $\alpha$ H3.X/Y (green, middle left) and H3S10ph (red, middle right) shows chromatin association of H3.X/Y signal. Overlay is shown on the right, scale bar equals 10  $\mu$ m. (E) Chromosome spreads of mitotically arrested U2OS cells show chromatin incorporation of H3.X/Y signal. Depicted is a projection of deconvolved widefield images of U2OS metaphase chromosome spreads co-stained with DAPI (DNA, blue, left) and  $\alpha$ H3.X/Y (green, middle). Overlay is shown on the right, inset shows an enlargement of a single chromosome, indicated by a red arrowhead. Scale bar equals 10  $\mu$ m. (F) Super-resolution 3D-SIM IF analysis of U2OS cells expressing low (left) or high (right) amounts of H3.X/Y co-stained with DAPI (blue) and  $\alpha$ H3.X/Y (green). Scale bar equals 5  $\mu$ m. Enlargements of boxed sections are depicted on the right with scale bar equaling 1  $\mu$ m. H3.X/Y signal is mostly found outside of DAPI-dense regions. In (B)-(D) and (F) confocal mid-sections are shown.

histones of any other cell line (Fig. 3.9A). These data are consistent with previous findings, as the size of this band would be expected for H3.Y and U2OS cells express mostly H3.Y mRNA (see Fig. 3.3A). Moreover, in confocal images of U2OS cells stained with  $\alpha$ H3.X/Y, a strong nuclear staining, co-localizing with DNA, was detected in some few cells but not in any other cell line (Fig. 3.9B, arrowhead). However, in all human cells, a dotted H3.X/Y staining associated with the nuclear envelope was visible (Fig. 3.9B and section 3.8). In contrast, mouse and rat cells, which were used as negative controls, do not display any H3.X/Y signal (Fig. 3.9C). In H3.X/Y expressing mitotic U2OS cells as well as in chromosome spreads of mitotically arrested H3.X/Y expressing U2OS cells, H3.X/Y signal is associated with condensed chromosomes, arguing for a stable chromatin incorporation of endogenous H3.X/Y protein (Fig. 3.9D,E). As seen for HA-tagged novel variants, H3.X/Y staining shows a distinct distribution along chromosome arms (Fig. 3.9E). To shed light on the sub-nuclear localization of endogenous H3.X/Y protein, our collaborator Lothar Schermelleh performed super-resolution imaging with 3-dimensional structured illumination microscopy (3D-SIM) analysis (Gustafsson et al., 2008; Schermelleh et al., 2008). This method provides the possibility to acquire images with a resolution below the diffraction limit of conventional optical microscopes and therefore allows to determine sub-nuclear localization of proteins more accurately (Fig. A.3, Appendix). In U2OS cells, co-stained with  $\alpha$ H3.X/Y and DAPI, this technique finds the H3.X/Y signal primarily outside of DAPI-dense region, irrespective of H3.X/Y expression levels (Fig. 3.9F). This finding suggests an association of H3.X/Y with less condensed and more euchromatic areas.

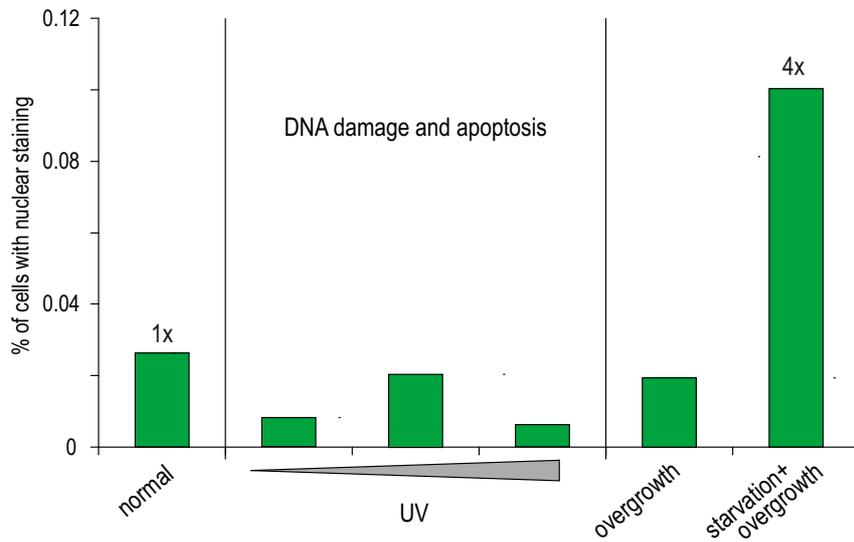

In summary, these data show that endogenous H3.X and/or H3.Y protein is expressed in U2OS cells. It localizes to the nucleus, is incorporated into chromatin and seems to be associated with more euchromatic areas.

## **3.5 Induction of endogenous H3.X/Y expression in U2OS cells**

### **3.5.1 Increase in H3.X/Y expressing U2OS cells through nutritional and proliferative stress**

Previous analyses of U2OS cell samples have shown that only less than 0.1 % of cells show a general nuclear H3.X/Y staining in IF microscopy. In addition, this percentage as well as the amount of H3.X+Y mRNA, determined in qPCR measurements, varies considerably between biological replicates. Wondering what causes these fluctuations, some kind of stress stimulus was hypothesized to trigger H3.X/Y expression in U2OS cells. Together with Silke Mildner, a

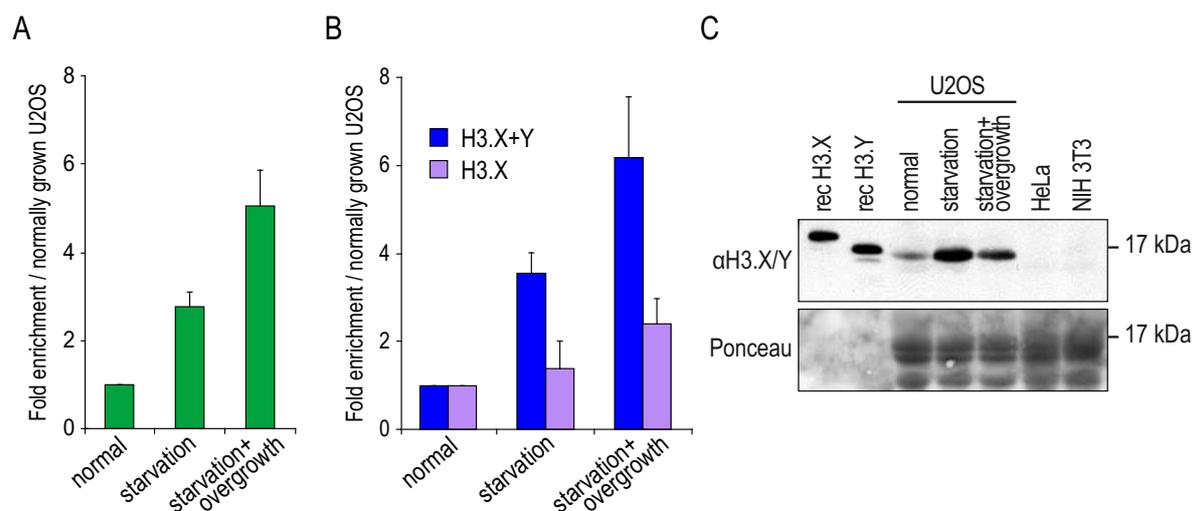

diploma student in the Hake group, whom I supervised, I set out to test this hypothesis. The first set of stress conditions tested were UV irradiation, causing DNA damage and at higher doses apoptosis, and proliferative stress or proliferative stress concomitant with starvation. UV treatment did not change the number of U2OS cells showing a general nuclear  $\alpha$ H3.X/Y staining (Fig. 3.10) nor did hydroxyurea or etoposide, which induce DNA damage via other pathways than UV (data not shown). Interestingly, proliferative and nutritional stress together but not proliferative stress alone led to a 4-fold increase in the number of  $\alpha$ H3.X/Y stained nuclei (Fig. 3.10).

**Figure 3.10. Test of different stress conditions as trigger for H3.X/Y expression in U2OS cells.** U2OS cells were grown under different stress conditions for 8 days (normal, overgrowth or starvation and overgrowth) or treated with different doses of UV light to induce DNA damage and apoptosis (for details see section 2.3.1.2). Cells were co-stained with DAPI (DNA) and  $\alpha$ H3.X/Y and percentage of cells showing a general nuclear staining was calculated and plotted (for details see section 2.3.4). Starvation and overgrowth but not overgrowth alone leads to an increase in the number of H3.X/Y expressing cells, whereas DNA damage and apoptosis does not show any effect.

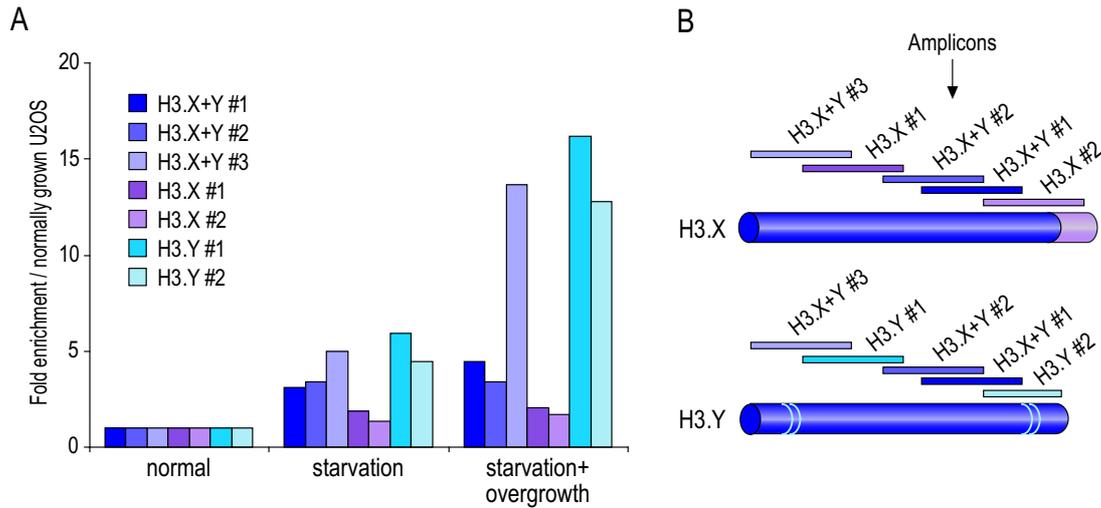

Based on these findings, we next examined if starvation alone or only together with high cell density can lead to an increase in U2OS cells positive for  $\alpha$ H3.X/Y staining. We cultivated U2OS cells for 8 days under different stress conditions (normal, starvation or starvation and overgrowth), calculated the percentage of cells with general nuclear  $\alpha$ H3.X/Y staining from IF microscopy data, quantified H3.X/Y mRNA levels by qPCR and analyzed H3.X/Y protein levels by Western blotting using  $\alpha$ H3.X/Y. With these experiments we could reproducibly show that starvation and overgrowth (SO) increases the number of cells with  $\alpha$ H3.X/Y-positive nuclei by approximately 6-fold, whereas starvation (S) alone only leads to a 3-fold increase (Fig. 3.11A). H3.X+Y mRNA levels are likewise affected (Fig. 3.11B). In Western blot analysis of acid extracted histones, the 17 kDa band, only faintly visible in the lane with

histones from normally grown U2OS cells, appears much stronger after both stress treatments (Fig. 3.11C). Comparison with recombinant H3.X and H3.Y proteins loaded as size markers and positive controls, suggests that specifically H3.Y rather than H3.X protein levels are increased. This is in accordance with the mRNA data that show a stronger enrichment of H3.X+Y than H3.X amplicons, thereby arguing that these stress stimuli act particularly on H3.Y expression.

**Figure 3.11. Increase of H3.X/Y expressing U2OS cells by nutritional and proliferative stress.** U2OS cells were grown for 8 days under different stress conditions (normal, starvation or starvation and overgrowth) and subsequently analyzed for number of cells showing a general nuclear H3.X/Y staining, H3.X/Y mRNA and protein levels. (A) Cells were co-stained with DAPI (DNA) and  $\alpha$ H3.X/Y and percentage of cells showing a general nuclear staining was calculated and plotted (for details see section 2.3.4). Starvation and overgrowth, and to a lesser extent starvation alone, increases number of cells with general nuclear H3.X/Y staining. Error bars represent SEM of three independent biological experiments. (B) H3.X/Y mRNA levels were quantified by qPCR using cDNA. H3.X+Y (blue) and H3.X (purple) levels are shown relative to HPRT1 and HMBS and normalized to normally grown U2OS cells. Nutritional and proliferative stress significantly increases H3.X+Y, but not H3.X levels. Error bars represent SEM of three independent biological experiments. (C) Acid extracted histones were analyzed for H3.X/Y protein levels by Western blotting using  $\alpha$ H3.X/Y antibody (top). Recombinant H3.X and H3.Y proteins served as positive, acid extracted histones from HeLa and mouse NIH3T3 cells as negative controls. Ponceau S staining ensured equal protein loading (bottom). Starvation with and without overgrowth leads to an increase of a 17 kDa band in U2OS cells. One representative blot of three independent biological experiments is shown.

To further validate that indeed H3.Y expression is mostly affected by S and SO treatment, qPCR analysis with cDNA from one biological replicate of the above stress experiments (see Fig. 3.11) was performed, using several primer pairs targeting H3.X and H3.Y mRNA or specifically the one or the other. Amplicons were chosen to span the complete coding sequence of both variants (Fig. 3.12B). H3.X mRNA levels stay virtually constant upon S and SO treatment, whereas H3.Y-specific as well as some of the H3.X+Y-specific amplicons show a strong enrichment (Fig. 3.12A), confirming previous findings. Primer pair H3.X+Y #3 has previously been identified as the most sensitive of the H3.X+Y primer pairs. For data de-

**Figure 3.12. Evaluation of inducible endogenous H3.X and H3.Y expression.**

(A) qPCR analysis of cDNA from U2OS cells grown under different stress conditions using different primer pairs for H3.X and H3.Y. The result of one of the three biological replicates depicted in Fig. 3.11 is shown. (B) Amplicons generated by three H3.X+Y-specific (shades of blue), two H3.X-specific (shades of purple) and two H3.Y-specific (shades of cyan) primer pairs span the complete coding regions ("primer-walk"). For primer sequences see Table A.1.

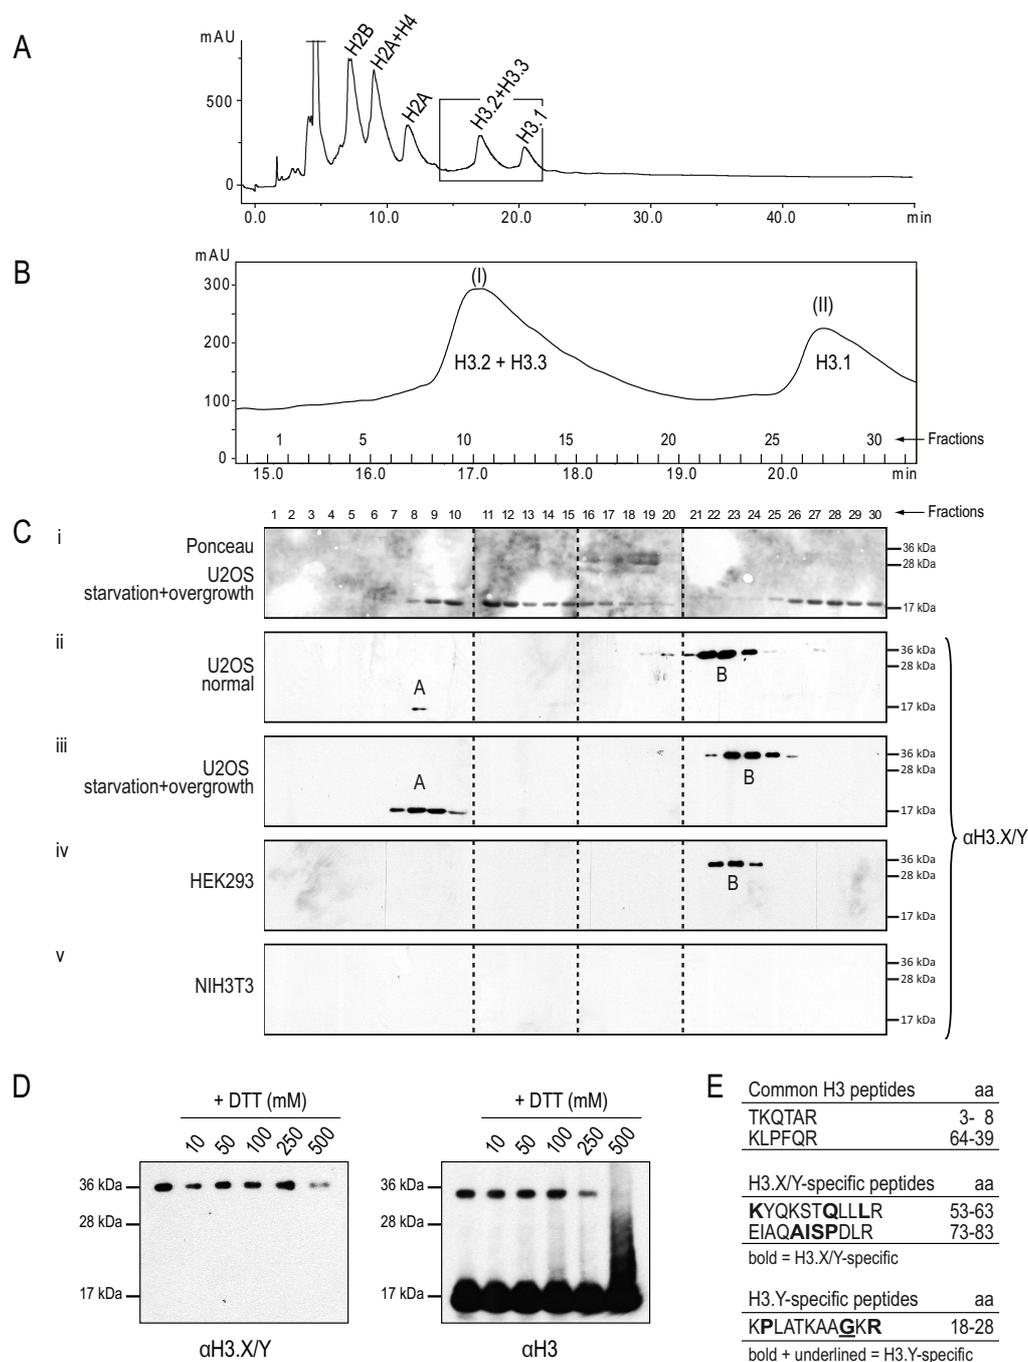

pictured in Figs. 3.3A and 3.11B, primer pairs H3.X+Y #2 and H3.X #2 have been used.

To assess the question which factor(s) in the growth medium cause the observed effects, cells were also scored for  $\alpha$ H3.X/Y-staining after serum-starvation, amino acid-depletion or growth under reduced oxygen levels, none of which had a reproducible effect on H3.X/Y expression (data not shown).

In summary, these data show a direct correlation between  $\alpha$ H3.X/Y nuclear staining, H3.X/Y mRNA and protein levels, all being upregulated by starvation and overgrowth and to a lesser extent starvation alone. Furthermore, they suggest that particularly H3.Y expression is positively affected by these treatments.

### 3.5.2 Increase of endogenous H3.Y protein expression in U2OS cells after SO treatment

SO treatment increases the number of cells with  $\alpha$ H3.X/Y nuclear staining, presumably caused by enhanced expression of H3.Y. To confirm this assumption, novel histone H3 variants were purified from U2OS cells and analyzed using mass spectrometry. Total histones were isolated from normally grown or SO treated U2OS cells and separated using reversed phase-high performance liquid chromatography (RP-HPLC) (Fig. 3.13A). Histone H3 variants elute in two peaks: peak I contains H3.2 and H3.3 whereas peak II contains only H3.1 protein (Fig. 3.13B) (Hake et al., 2006). Fractions 1-30, corresponding to histone H3 peaks,

**Figure 3.13. Purification and identification of endogenous H3.Y protein.**

Acid extracted histones of normally grown and SO treated U2OS as well as HEK293 and mouse NIH3T3 cells were separated by RP-HPLC and fractions containing H3 variants were analyzed by Western blotting and mass spectrometry. (A) Typical histone RP-HPLC peak profile. Box indicates fractions used for analysis. (B) An enlargement of boxed section marked in (A) is shown. (C) Western blots with fractions 1-30 (marked in (B)) from different cell lines using  $\alpha$ H3.X/Y antibody, show a weak band at 17 kDa in normally grown U2OS cells (A band, ii), which is strongly enhanced after SO treatment (A bands, iii) and not visible in any other cell line. Region B bands ( $\sim$ 35 kDa) are present in all human but not in mouse cells (ii-iv versus v). Ponceau S staining of U2OS SO membranes visualizes protein content in individual fractions (i). Dotted lines indicate that intervening lanes have been spliced out. (D) Fractions containing region B bands and fractions containing H3.1, H3.2 and H3.3 were treated with different amounts of DTT. Western blotting using  $\alpha$ H3.X/Y for region B band fractions (left) and  $\alpha$ H3 for H3 fractions (right) shows dissociation of H3 dimers but no effect on region B bands. (E) List of H3 and H3.X/Y peptides identified in combined region A fractions of normally grown and SO treated U2OS cells in LC-MS/MS analyses. Amino acids marked in bold are specific for H3.X and H3.Y, bold and underlined amino acid is H3.Y-specific. For MS/MS spectra see Fig. A.4.

were analyzed on Western blots probed with  $\alpha$ H3.X/Y. Ponceau staining of membranes with histones from SO treated U2OS cells, shows amount of canonical H3 present in individual fractions (Fig. 3.13Ci). Proteins detected by  $\alpha$ H3.X/Y elute right before peaks I and II (Fig. 3.13Cii,iii). As expected, a faint 17 kDa band, indicative of H3.Y, can be observed in normally grown U2OS cells and is strongly enhanced in SO treated cells (region A bands in Fig. 3.13Cii and iii). In addition, a 35 kDa protein, showing the same intensity under both growth conditions, is also detected by  $\alpha$ H3.X/Y (region B bands in Fig. 3.13Cii and iii). For comparison, total histones from human HEK293 and mouse NIH3T3 cells were RP-HPLC-purified and corresponding fractions analyzed on Western blots. Both cell lines show no signal for region A bands, however, a strong region B band signal can be observed in HEK293 cells, proposing the corresponding protein to be present in all human but not in mouse cells (Fig. 3.13Civ,v). The size of the protein causing region B band signals is approximately twice the size of H3.X and H3.Y, giving rise to the idea that it might constitute a homo- or heterodimer of novel H3 variants. To test this hypothesis, region B band fractions and a mixture of peak I and II fractions were treated with increasing amounts of DTT to reduce disulfide bonds and thereby separate potential H3 dimers. Peak I and II fractions contain minimal amounts of H3 dimers, which can be separated using high DTT concentrations (Fig. 3.13D). No such effect on proteins in region B band fractions can be observed, arguing against a dimerization of novel H3 variants. Region A, as well as region B band fractions, were subjected to mass spectrometrical analysis using nano-ESI-LC-MS/MS. For proteins present in region B band fractions only one single peptide corresponding to H3.X/Y (aa 53-63) could be observed among several others, rendering the analysis of these fractions inconclusive. However, for proteins present in region A band fractions, two H3.X/Y-specific (aa 53-63 and aa 73-83), as well as one H3.Y-specific (aa 18-28) peptide, could be identified in addition to common H3 peptides in two biological replicates of SO treated and in normally grown U2OS cells (Fig. 3.13E and Fig. A.4A-C, Appendix). Interestingly, the H3.Y-specific peptide was also found to be acetylated on K18, K23 and K27 in some cases in both SO treated and normally grown U2OS cell samples (Fig. A.4D,E, Appendix). These PTMs are also present in canonical H3 variants, indicating that H3.Y was likely part of a nucleosome and present in chromatin fibers.

In summary, these data show that posttranslationally modified H3.Y is expressed in U2OS cells and that its levels are increased upon SO treatment.

### 3.6 Effects of H3.Y on gene expression

Previous experiments have shown that *H3.X* and *H3.Y* genes are expressed *in vivo* and that at least H3.Y constitutes a novel histone H3 variant. To examine the biological function(s) of H3.Y expression, RNA expression profiles of cells expressing enhanced or reduced levels of H3.Y have been generated. For both sets of experiments the hybridization was carried out by Dietmar Martin and Kerstin Maier of the Gene Center Affymetrix Microarray Platform (LMU Munich, Cramer Laboratory) and data analysis was performed by our collaborator Tobias Straub (LMU Munich, Becker Laboratory).

#### 3.6.1 De-regulation of genes mainly implicated in growth control, survival or differentiation pathways in HeLa HA-H3.Y cells

The number of H3.Y expressing U2OS cells varies considerably between different samples. Therefore, the initial idea was to use HeLa cells constitutively expressing HA-tagged H3.Y and compare their RNA expression profile with that of empty vector transfected HeLa cells. Total RNA was isolated from two independently selected HeLa HA-H3.Y and HeLa empty vector cell populations, respectively, and hybridized to Affymetrix Human Gene 1.0 ST arrays. In HeLa HA-H3.Y cells, 119 genes were significantly up- and 73 significantly down-regulated (local false discovery rate cutoff 0.2). The most upregulated gene was *H3.Y* (LOC391769), thereby verifying the sensitivity and accuracy of the assay. Gene ontology (GO) enrichment analysis revealed that affected genes are mainly implicated in growth control, survival or

**Figure 3.14. GO enrichment analysis of de-regulated genes in HeLa HA-H3.Y cells.**

List of GO terms resulting from an enrichment analysis of significantly up- (A) or down- (B) regulated genes in HeLa HA-H3.Y relative to HeLa empty vector cells as determined by microarray analysis. Size = total number of genes analyzed in this node (GO term), ExpCount = number of "responders" expected (entering the term by chance), Count = actual number of "responders" found in the node.

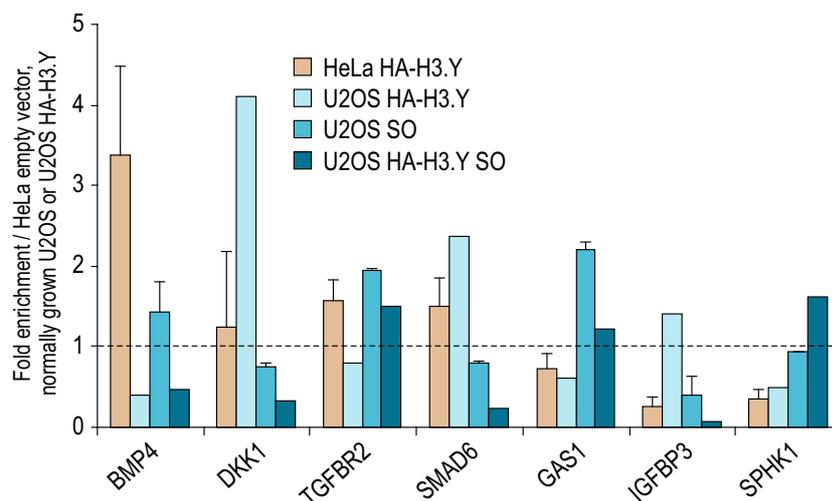

differentiation pathways (Fig. 3.14). Before analyzing the biological meaning of this result, several controls have been performed. As the array used is rather new, the first step was to validate the microarray results for a selection of genes. 9 of the strongest "responders" were chosen as well as the 7 most de-regulated genes in the listed GO groups. cDNA was synthesized from the same RNA used for microarray analysis, expression levels were quantified by qPCR relative to HPRT1 and HMBS and results were normalized to empty vector transfected HeLa cells. Comparison of microarray and qPCR data for these loci shows a general correlation of expression data (Fig. 3.15, left). However, depending on the localization of the primers and the uniformity of the data determined from individual probesets, the actual results differ to a certain extent. Another important question is the distinction

**Figure 3.15. Gene expression levels in HeLa cells stably expressing HA-tagged H3 variants.**

Comparative qPCR analysis of cDNA from HeLa cells stably expressing HA-tagged H3.1, H3.3 or H3.Y with primer pairs for two subsets of genes, de-regulated in HeLa HA-H3.Y relative to HeLa empty vector cells. On the left, microarray data normalized to HeLa empty vector and on the right, qPCR results relative to HPRT1 and HMBS and normalized to HeLa empty vector are plotted. Error bars represent SEM of two independently selected HeLa cell populations. Subset 1 genes (top) were selected from the strongest "responders" in microarray analysis of HeLa HA-H3.Y compared to HeLa empty vector cells. Subset 2 genes (bottom) are significantly de-regulated in HeLa HA-H3.Y cells and part of GO groups listed in Fig. 3.14.

between H3.Y-specific effects and effects that result from the constitutive expression of any tagged H3 variant. Therefore, the same loci used for validation of the method, were analyzed for their expression levels in HeLa HA-H3.1 and -H3.3 cells using qPCR. Some of the genes strongly de-regulated in HeLa HA-H3.Y cells show almost no change in HeLa HA-H3.1 and -H3.3 cells (e.g. APLF), arguing for an H3.Y-specific effect, but several other genes, such as CXCL16 or IGFBP3, are de-regulated similarly in all three cell lines (Fig. 3.15, right). As these results make it impossible to deduce a general biological meaning from the expression data in HeLa HA-H3.Y cells without having the corresponding data for HeLa cells expressing other H3 variants, we decided to compare expression levels of individual de-regulated genes in HeLa HA-H3.Y with normally grown U2OS HA-H3.Y cells and U2OS and U2OS HA-H3.Y cells grown under SO conditions for 8 days. With this dataset, cell line dependent and general effects of HA-H3.Y can be distinguished from each other. Furthermore, effects of SO treatment can be compared to those caused by constitutive HA-H3.Y expression. Expression levels determined by qPCR are shown relative to HPRT1 and HMBS and normalized to U2OS empty vector cells, normally grown U2OS and U2OS HA-H3.Y cells, respectively. For HeLa HA-H3.Y, qPCR data shown in Fig. 3.15 (bottom) are depicted (Fig. 3.16). Comparison of expression levels in HeLa HA-H3.Y and U2OS HA-H3.Y cells, shows huge differences, arguing for a strong influence of the cellular background on HA-H3.Y function (Fig. 3.16, light brown vs. light blue bars). Dickkopf 1 (DKK1) for example, shows only mild up-regulation in HeLa

**Figure 3.16. Influences of HA-H3.Y expression and SO treatment on gene expression.**

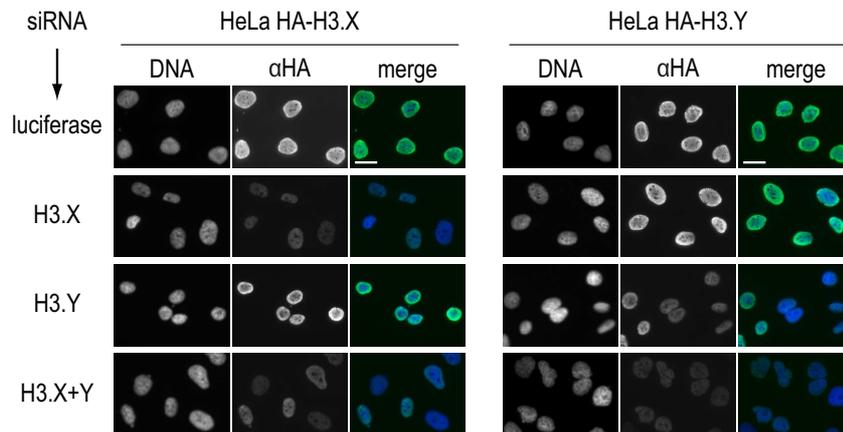

Comparative qPCR analysis of cDNA from HeLa HA-H3.Y, U2OS HA-H3.Y, U2OS SO and U2OS HA-H3.Y SO cells with primer pairs for subset 2 genes (see Fig. 3.15) shows cell line dependent effects of HA-H3.Y expression and no consistent synergistic effects of HA-H3.Y expression and SO treatment. Expression levels are calculated relative to HPRT1 and HMBS and shown as fold enrichment over HeLa empty vector, U2OS empty vector, normally grown U2OS and normally grown U2OS HA-H3.Y cells, respectively. Error bars represent SEM of two independently selected HeLa cell populations (HeLa HA-H3.Y) or two biological replicates (U2OS SO).

HA-H3.Y cells whereas levels are strongly increased in U2OS HA-H3.Y cells. As DKK1 is implicated in bone formation (Pinzone et al., 2009) and U2OS cells constitute bone derived cells, this difference is most likely caused by basic differences between HeLa and U2OS cells. In contrast to these extreme discrepancies, growth arrest specific protein 1 (GAS1) and the transforming growth factor  $\beta$  (TGF $\beta$ )-target sphingosine kinase (SPHK1) (Donati et al., 2009) show reduced levels in both cell lines, arguing for H3.Y-specific effects. Based on the finding that H3.Y expression is induced in U2OS cells after SO treatment, we hypothesized that HA-H3.Y expression and SO treatment have similar effects. However, this is not the case for any of the genes analyzed (Fig. 3.16, light vs. middle blue bars). The cause for this discrepancy is presumably that SO treatment affects the expression of many genes other than H3.Y. Analyzing the data with regard to synergistic effects of HA-H3.Y expression and SO treatment, the emerging picture is quite complex (Fig. 3.16, middle vs. dark blue bars). For several genes, such as SMAD6, an inhibitor of the TGF $\beta$ -cascade (Moustakas and Heldin, 2009) or insulin-like growth factor binding protein 3 (IGFBP3), which is known to stimulate TGF $\beta$ -signaling via the SMAD-pathway (Fanayan et al., 2000, 2002), SO treatment causes a reduction of gene expression, which is stronger when in addition HA-H3.Y is expressed, thereby showing a synergistic effect. For other genes, HA-H3.Y expression seems to do the contrary by attenuating the effect of SO treatment. Examples are GAS1 and TGF $\beta$  receptor 2 (TGFBR2) which activates the TGF $\beta$ -cascade (Moustakas and Heldin, 2009). Taken together, these data show that H3.Y influences gene expression in a cell type specific manner. Since HeLa cells do not express endogenous H3.Y (see Fig. 3.3A), it is impossible to deduce the biological role of this novel variant from HeLa HA-H3.Y expression data.

### 3.6.2 Impairment of cell proliferation in U2OS cells after knockdown of H3.Y or H3.X+Y

To gain a deeper insight into the biological function(s) of H3.Y, U2OS cells with reduced endogenous H3.Y mRNA and protein levels after RNA interference (RNAi) -knockdown were used for global transcriptome analysis, a system closer to the *in vivo* situation than the constitutive expression of tagged protein. Due to the high sequence similarity of H3.X and H3.Y (see Fig. A.1, Appendix), only one small interfering RNA (siRNA) specifically targeting H3.X and one targeting H3.Y could be designed. In addition, one siRNA directed against both mRNAs (H3.X+Y) was used and control knockdowns were performed using luciferase targeting siRNA, a gene not present in human cells (for siRNA sequences see Table A.3). To test specificity of siRNAs, HeLa HA-H3.X and -H3.Y cells were transfected with siRNAs and co-stained with  $\alpha$ HA and DAPI 4 days later. IF microscopy analysis shows that luciferase

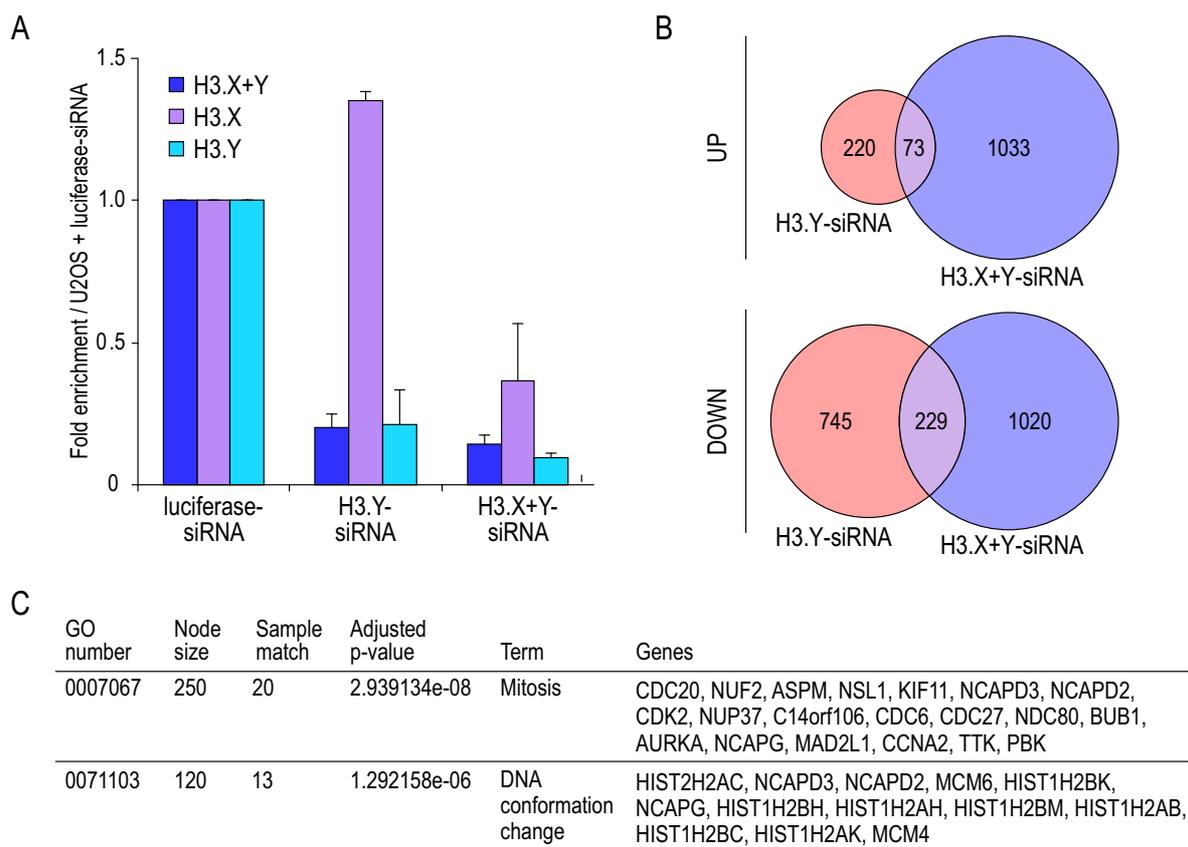

control knockdown does not affect HA signals in both cell lines, whereas fluorescence signal is lost in both cases after transfection with H3.X+Y-siRNA (Fig. 3.17). H3.X-siRNA specifically reduces fluorescence signal in HA-H3.X but not in HA-H3.Y expressing HeLa cells, H3.Y-siRNA shows reversed specificity.

**Figure 3.17. Evaluation of H3.X/Y siRNA specificity.**

IF microscopy analysis of HeLa HA-H3.X (left) and -H3.Y (right) cells 4 days after siRNA transfection, shows specificity of H3.X-, H3.Y- and H3.X+Y-siRNAs. Cells were co-stained with DAPI (DNA, blue, left) and  $\alpha$ HA (green, middle), overlay is shown on the right (merge). Scale bar equals 20  $\mu$ m.

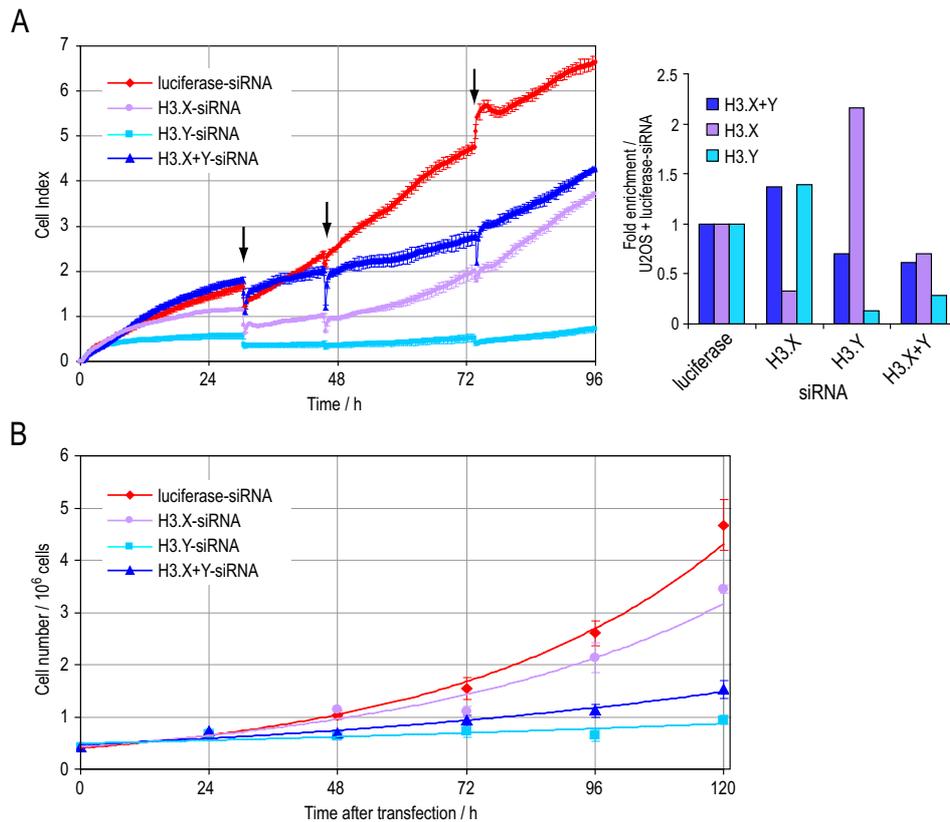

For global transcriptome analysis, two independent double siRNA-knockdowns of H3.Y, H3.X+Y and luciferase control in SO treated U2OS cells were performed. RNA was isolated and knockdown efficiency monitored by qPCR analysis (Fig. 3.18A). RNA was hybridized to Affymetrix Human Gene 1.0 ST arrays and expression levels in H3.Y and H3.X+Y relative to luciferase knockdown cells were determined. In H3.Y-siRNA knockdown cells, 293 genes were up- and 974 genes down-regulated, whereas cells treated with H3.X+Y-specific siRNAs showed 1106 up- and 1249 down-regulated genes (local false discovery rate cutoff 0.2). To eliminate H3.X-specific and off-target effects, genes de-regulated after both knockdowns were identified. Numbers of shared up- (73) and down-regulated (229) genes are depicted in Venn diagrams (Fig. 3.18B). GO enrichment analysis of overlapping genes revealed a long list of affected GO groups comprising, among others, cell cycle-controlling, chromatin organization, metabolic and signaling pathways (Fig. A.5, Appendix). To elucidate the connection between these groups, a simplified GO list was generated, containing major groups affected by the applied treatment. For shared up-regulated genes no such group could be identified, but down-regulated genes turned out to be mostly implicated in mitosis and DNA conformation changes (Fig. 3.18C). Since H3.Y seems to be implicated in mitosis and we previously noticed a reduction in cell number after H3.Y and H3.X+Y knock-down, U2OS cells were analyzed for their proliferation capacity after knockdown of H3.Y or H3.X+Y. Treatment

**Figure 3.18. mRNA expression profiling of U2OS cells after H3.Y or H3.X+Y knockdown.**

Total RNA of SO treated U2OS cells transfected twice with siRNAs targeting luciferase, H3.Y or H3.X+Y, was used for global transcriptome analysis 4 days after first transfection. (A) qPCR analysis of H3.X and H3.Y levels in cDNA, transcribed from the same RNA used for microarray analysis, verifies efficient knockdown of H3.Y or H3.X+Y. Data is shown relative to HPRT1 and HMBS and normalized to luciferase-siRNA transfected cells. Error bars represent SEM of two independent biological experiments. (B) Venn diagrams show numbers of genes significantly up- (top) or down- (bottom) regulated after H3.Y (red) or H3.X+Y (blue) knockdown as identified by microarray analysis of two independent biological replicates when compared to luciferase control knockdown. Overlap represents number of genes that are de-regulated after both knockdowns (purple). (C) Simplified GO list of genes significantly down-regulated after both knockdowns. For a complete list see Fig. A.5. Node size = total number of genes analyzed in this node (GO term).

with H3.X-siRNA was also included to determine if novel H3 variants in general play a role in cell cycle control or if this is specific for H3.Y. Cells were transfected twice with siRNAs targeting luciferase (control), H3.X, H3.Y or H3.X+Y, seeded in E-plates one day after the second transfection and cell growth was monitored quantitatively over 96 h using a RTCA DP Analyzer. Growth curves clearly show that knockdown of both novel variants, but not the control knockdown, affects cell growth, although the influence of H3.Y seems to be stronger than that of H3.X (Fig. 3.19A, left). qPCR analysis of H3.X/Y levels 4 days after first transfection, shows knockdown efficiencies (Fig. 3.19A, right). Interestingly, single siRNA-knockdown of H3.X and H3.Y in HeLa cells, which do not express detectable amounts of H3.X/Y mRNA (see Fig. 3.3A), shows a similar growth phenotype for H3.Y, but hardly any effect of H3.X-siRNA knockdown (Fig. 3.19B). Cells were counted every day starting one day prior to transfection.

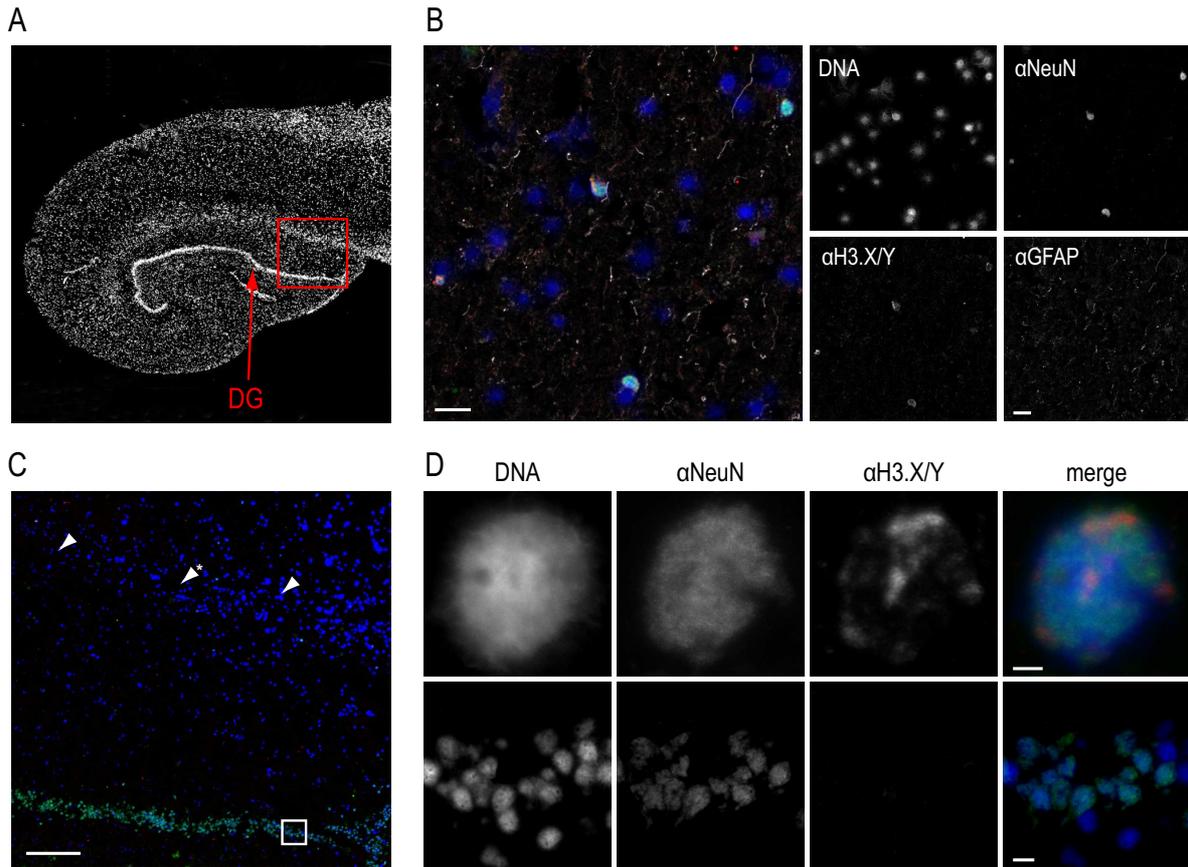

**Figure 3.19. Influence of H3.X and/or H3.Y knockdown on proliferation capacity.**

(A) U2OS cells were transfected twice with siRNAs targeting luciferase (control), H3.X, H3.Y and H3.X+Y and seeded in E-plates one day after the second transfection ( $t = 0$  h). Cell growth was monitored over 4 days using the RTCA DP Analyzer. Error bars represent standard deviation of 4 (luciferase, H3.Y) or 2 (H3.X, H3.X+Y) technical replicates. Arrows indicate changes of growth medium. qPCR analysis of cDNA, synthesized from RNA extracted 4 days after first transfection, shows knockdown efficiency (right). H3.X/Y levels are depicted relative to HPRT1 and HMBS and normalized to luciferase control. (B) HeLa cells were transfected once with siRNAs targeting luciferase (control), H3.X, H3.Y and H3.X+Y. Cells were counted with the CASY Counter one day prior to transfection ( $t = 0$  h) and for the following 5 days. Error bars represent standard deviation of 3 wells processed in parallel. In U2OS cells, knockdown of H3.X, H3.Y and H3.X+Y impair cell growth, whereas in HeLa cells only the knockdowns of H3.Y and H3.X+Y have this effect.

In summary, it could be shown that the depletion of H3.Y in U2OS cells has a strong effect on cell proliferation which is also reflected in the de-regulation of genes implicated in mitosis. Depletion of H3.X also has an impact on cell growth in U2OS but not in HeLa cells, whereas H3.Y-knockdown has a similar phenotype in both cell lines.

### 3.7 Expression of endogenous H3.X/Y protein in human brain

So far, expression of endogenous H3.Y protein has only been shown for U2OS cells. However, expression of H3.Y and partially also H3.X mRNA has been detected in different human tissues (see Fig. 3.3C), suggesting that also the corresponding protein(s) might be expressed in

**Figure 3.20. H3.X/Y expression in human brain.**

Confocal imaging of commercially available human hippocampus sections, co-stained with  $\alpha$ H3.X/Y (red),  $\alpha$ NeuN (neuronal marker, green),  $\alpha$ GFAP (astrocyte marker, white) and DAPI (DNA, blue), reveals H3.X/Y expression in a sub-population of neurons outside the dentate gyrus. (A) Overview picture of human hippocampus stained with DAPI (DNA). Individual 5x-pictures were merged using the photomerge function of Adobe Photoshop to create this view. The characteristic band of neurons (dentate gyrus = DG) is indicated with an arrow. (B) Area above DG with several H3.X/Y positive cells. Note that H3.X/Y overlaps with NeuN but not GFAP signal. Scale bar equals 20  $\mu$ m. One representative staining out of three is shown. (C) Enlargement of boxed area indicated in (A). DG is visible at the bottom, arrowheads mark H3.X/Y positive neuronal cells. Scale bar equals 200  $\mu$ m. One representative staining out of three is shown. (D) Higher resolution image of H3.X/Y positive cell, marked with an asterisk in (C), shows distinct sub-nuclear localization of H3.X/Y signal (top). Scale bar equals 2  $\mu$ m. Enlargement of boxed section in (C) shows neurons in the DG without H3.X/Y staining (bottom). Scale bar equals 10  $\mu$ m.

these tissues. Taking into account that many primate-specific genes are expressed in brain and reproductive organs (Tay et al., 2009) we chose to analyze commercially available sections of human hippocampus in IF to address the question of endogenous H3.X/Y protein expression in human tissues.

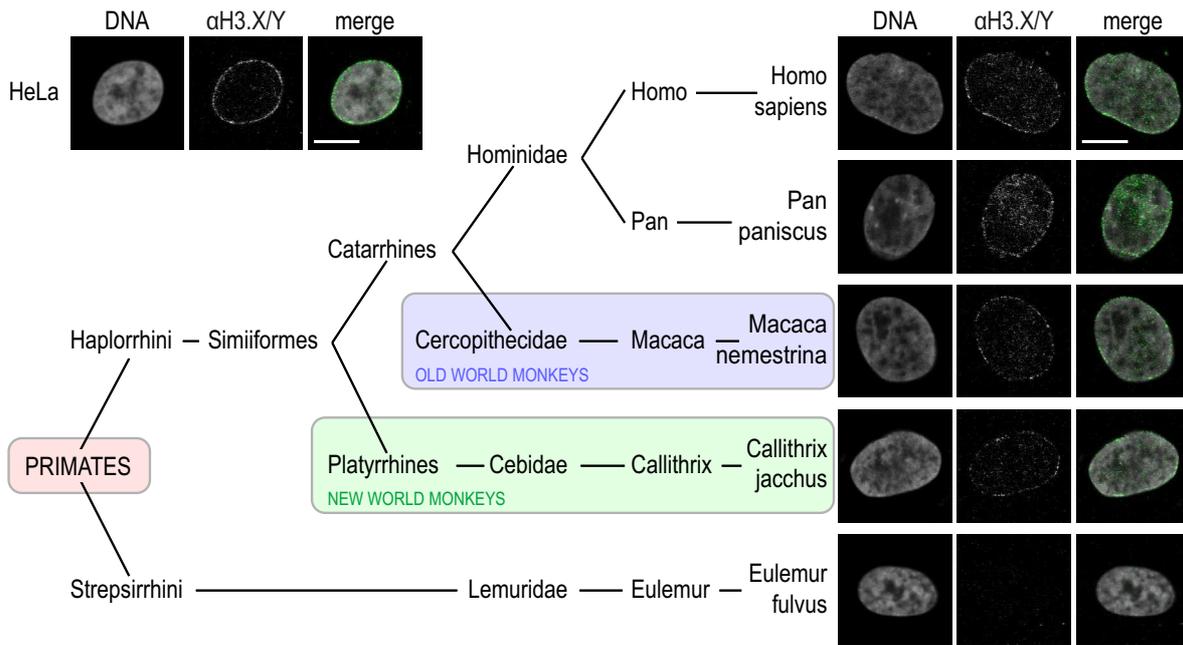

Sections were co-stained with  $\alpha$ H3.X/Y, DAPI and in addition with  $\alpha$ NeuN, marking neurons and  $\alpha$ GFAP, staining astrocytes. Merged confocal images of DAPI-stained tissue with 5x-magnification shows organization of this brain area with the band of neuron nuclei indicating the dentate gyrus (DG) (Fig. 3.20A). Several nuclei stain positive with  $\alpha$ H3.X/Y, all of them also showing a NeuN- but no GFAP-signal, identifying them as neurons (Fig. 3.20B). Higher

resolution images of boxed section marked in Fig. 3.20A finds some few  $\alpha$ H3.X/Y stained cells, all localizing outside the DG (Fig. 3.20C, arrowheads). This finding is in accordance with our observation that only few U2OS cells show a general nuclear  $\alpha$ H3.X/Y staining. Surprisingly, a close-up view of the H3.X/Y expressing cell indicated with an asterisk in Fig. 3.20C, shows a distinct sub-nuclear localization pattern of H3.X/Y protein, which is different to the staining in U2OS cells (Fig. 3.20D, top row). Neurons in the DG (boxed area in Fig. 3.20C) do not stain positive with  $\alpha$ H3.X/Y (Fig. 3.20D, bottom row).

Concluding, H3.X and/or H3.Y protein is expressed in a subpopulation of neurons in the human hippocampus, highlighting the possibility that novel histone H3 variants might have cell-type specific functions. H3.X/Y protein(s) localizes solely to the nucleus and shows a distinct sub-nuclear localization pattern.

### 3.8 Expression of endogenous H3.X/Y protein in different primate species

*H3.X* and *H3.Y* constitute primate-specific genes. For humans, it could be shown that they encode for novel histone H3 variants and have an impact on the regulation of many genes implicated in cell cycle progression, but nothing is known about their expression and function in other primates. To address this question, primary fibroblasts from several primate species, each of them representing another branch of the phylogenetic tree of the primate lineage, were stained with  $\alpha$ H3.X/Y and analyzed using confocal microscopy. Although none of the cells shows a general nuclear staining, as observed for some few cells in U2OS samples (see Fig. 3.9B), most of them do show the dotted H3.X/Y staining associated with the nuclear envelope (Fig. 3.21). Interestingly, the only cells that do not show this pattern, are derived from *Eulemur fulvus*, which is the most distantly related species to humans in this set, suggesting that *H3.X* and *H3.Y* have either evolved after the separation of the primate lineage in Haplorrhini and Strepsirrhini or the antibody binding site has been destroyed by mutations in this species. Since mouse and rat cells do not show this dotted  $\alpha$ H3.X/Y staining (see Fig. 3.9C) and the  $\alpha$ H3.X/Y antibody has been shown to be highly specific (see Fig. 3.8), it appears reasonable to think that this signal originates from some kind of H3.X/Y protein. Fueling this idea is the fact that the annotation of the *H3.X* locus has changed several times over the last years, predicting different splice forms (Fig. A.6, Appendix). However, multiple attempts to clone these alternative H3.X transcripts from human cDNA or quantify them in qPCR analysis have failed, making the expression of particularly these splice forms unlikely

**Figure 3.21. H3.X/Y expression in primates.**

Confocal IF analysis of primary fibroblasts from different primates shows  $\alpha$ H3.X/Y staining in all species analyzed, except for lemurs. The phylogenetic tree of the primate lineage illustrates evolutionary relationships. Cells were co-stained with TO-PRO3 (DNA, gray, left) and  $\alpha$ H3.X/Y (green, middle). Overlay is shown on the right(merge). HeLa cells serve as positive control. Scale bar equals 10  $\mu$ m.

(data not shown). Furthermore, also purification and subsequent mass spectrometrical identification of the protein causing this dotted staining has so far not been successful (data not shown).

In summary,  $\alpha$ H3.X/Y antibody detects a protein associated with the nuclear envelope in several primate species. All attempts to confirm that this protein originates from the *H3.X* or *H3.Y* locus have failed so far. Future studies will have to reveal whether this staining is caused by another H3.X/Y protein species or is simply caused by a cross-reactivity of the antibody.

Taken together, it could be shown that H3.Y constitutes a novel histone H3 variant. H3.Y is expressed in human cells and specialized tissues, incorporated into chromatin, posttranslationally modified, and impacts the regulation of many genes implicated in cell cycle progression. The role of H3.X remains elusive and will have to be addressed in future experiments.

## 4 Discussion

### 4.1 *H3.X* and *H3.Y* are novel primate-specific histone genes

Searching the public database with the coding sequence of human histone *H3.1*, two novel histone H3 variant genes on human chromosome 5 have been identified, now termed *H3.X* and *H3.Y*. Consecutive database searches found *H3.X* and *H3.Y* genes also in the chimpanzee and the macaque genome but not in any other species. Although sequence data for other primates are not available yet, the absence of these genes in other mammals or even lower eukaryotes, suggests that they are primate-specific. Both genes are presumably duplications of one ancestral gene, as their sequences are highly similar (even in their 5' and 3' UTRs), with some differences in their putative promoter regions. Phylogenetic analysis of coding and 3' genomic sequences have revealed that *H3.X* and *H3.Y* are closer related to *H3.3* than to other H3 variant genes, proposing *H3.3* as the origin of *H3.X* and *H3.Y*, despite their lack of introns. The only primate-specific histone variant identified so far is H2BFWT, a protein only found in testis (Churikov et al., 2004). Interestingly, as observed for the *H2BFWT* locus, the genomic region syntenic to *H3.X* and *H3.Y* is much shorter in mouse and rat genomes, suggesting a common mechanism in the evolution of these variant genes.

### 4.2 Structure and behavior of H3.X and H3.Y proteins is similar to other H3 variants

Homology models of H3.X and H3.Y predict highly similar protein structures for novel and known H3. In the H3.X model, the extra C-terminus folds into an additional  $\alpha$ -helix (Fig. 3.5) that is proposed to be in close proximity to one part of the H2A acidic patch (D90, E91, E92). H2A exposes a stretch of acidic amino acids on the surface of the nucleosome. This negatively charged patch is bound by the positively charged H4 tail of an adjacent nucleosome (Luger et al., 1997), thereby promoting folding into higher-order structures (Caterino and Hayes, 2007). Interaction of the H3.X C-terminus with H2A at these sites could stabilize the nucleo-

some and promote a more open chromatin structure by preventing the H4 tails of neighboring nucleosomes from binding. Future studies, using *in vitro* reconstituted chromatin, will address this question.

Despite the exchange of several functionally important residues, tagged H3.X and H3.Y behave almost identical to H3.1, H3.2 and H3.3. Matching their high structural similarity, all variants are stably incorporated into chromatin and show a solely nuclear localization (Figs. 3.4, 3.6 and 3.7). The only difference that has been observed in mononucleosome IPs was that H3.X and H3.Y primarily form heterotypic nucleosomes *in vivo* (Fig. 3.6), whereas H3.1 and H3.3 are only found in homotypic nucleosomes (Tagami et al., 2004). A similar behavior has been described for H2A variants H2A.Z (Viens et al., 2006) and macroH2A (Chakravarthy and Luger, 2006) which both assemble preferentially together with canonical H2A in nucleosomes.

### 4.3 H3.X and H3.Y mRNA, but only H3.Y protein is expressed in human cells

H3.X and H3.Y mRNA are both transcribed in the human osteosarcoma cell line U2OS (Fig. 3.3A). Some few U2OS cells (<0.1%) show a general nuclear  $\alpha$ H3.X/Y staining. This staining has been shown to be caused by H3.Y, thereby identifying H3.Y as novel primate-specific H3 variant. So far, it has been impossible to verify the presence of endogenous H3.X protein, neither for the currently nor for previously annotated transcripts. The expression of H3.X mRNA, but not H3.X protein in U2OS cells could mean that H3.X is a pseudogene without any function. Alternatively, H3.X could also be a regulatory ncRNA, maybe even regulating H3.Y expression (for details see section 4.6). In addition to these transformed cells, expression of H3.Y mRNA at low but significant levels has been detected in some human bone, breast, lung and ovary tumor tissues, as well as in testis and certain areas of the brain. Interestingly, H3.X mRNA could also be observed, albeit only in testis and brain (Fig. 3.3C). Consistent with these findings, H3.X/Y protein has been shown to be expressed in a subpopulation of neurons in the human hippocampus (Fig. 3.20), a brain region which mainly functions in the formation of long-term memories and the process of learning (Lagali et al., 2010). Many primate-specific genes are expressed in the brain, but they are not particularly enriched in this organ relative to all transcripts. In contrast, they are preferentially expressed in the reproductive system, where they may contribute to speciation (Tay et al., 2009). Taken together, *H3.Y*, and maybe *H3.X*, constitute the first primate-specific histone variants that are also expressed outside testis, likely conferring specialized chromatin functions unique to

these higher vertebrates. Taking their tissue-specific expression patterns into account, it is tempting to speculate that H3.X and H3.Y might be involved in the process of speciation and, even more interestingly, in shaping higher brain functions.

#### **4.4 A putative H3.X/Y protein is associated with nuclear pores**

In all human cells and in cells of several closely related primate species, H3.X/Y protein staining can be observed at the nuclear envelope (Figs. 3.9B,F and 3.21). This staining co-localizes with nuclear pores as revealed by super-resolution IF analysis (Lothar Schermelleh, personal communication). Although it has so far not been possible to purify and analyze this H3.X/Y fraction in closer detail, the occurrence of this staining in primates but not in rodents (Fig. 3.9B vs. C), together with the presence of an additional  $\alpha$ H3.X/Y band in purified histones of human but not mouse cells (B bands in Fig. 3.13C i-iv vs. v), strongly argues for another H3.X/Y protein in primates. This protein has presumably a size of  $\sim$ 35 kDa and associates with nuclear pores. It is most likely not a dimer of H3.X and/or H3.Y (Fig. 3.13D) or one of the previously annotated H3.X transcripts. Regarding the function of this unusually localized H3.X/Y fraction, one tantalizing hypothesis is that it tethers certain chromatin areas to nuclear pores. In yeast, it is well established that nuclear pores are implicated in the activation of associated genes. Moreover, nuclear pores also act as boundaries that prevent spreading of active or repressive chromatin marks. Several studies and the high level of conservation of some of the involved proteins suggest a similar situation in human cells (Köhler and Hurt, 2010). Taken together, this could mean that H3.X/Y proteins at the nuclear pore function as "insulator histones" that prevent spreading of PTMs, such as the methylation of H3K79, through the absence of the respective modifiable amino acid.

#### **4.5 The number of H3.Y-expressing U2OS cells is increased by specific stress stimuli**

H3.Y mRNA and protein is expressed in some few U2OS cells under normal growth conditions, but the number of cells expressing this novel H3 variant can be increased by nutritional starvation in combination with high cell density. Testing whether SO treatment can induce H3.Y expression also in other cell lines, it turned out that the ability to grow to such high cell densities is special for U2OS cells. A hint towards the cause for this resistance came from microarray analyses of HeLa HA-H3.Y cells, where *GAS1* was among the down-regulated genes

(Fig. 3.15). GAS1 blocks cell cycle progression in various cells (Sal et al., 1992, 1994) and is highly expressed under growth arrest conditions (Schneider et al., 1988). Its downregulation leads to a loss of contact inhibition and allows higher cell density (Evdokiou and Cowled, 1998). Surprisingly, normally grown U2OS cells have approximately 4-fold lower endogenous GAS1 mRNA levels than empty vector transfected HeLa cells, giving a possible explanation for the growth behavior of this cell line.

Although the number of cells expressing endogenous H3.Y is low, the individual cell expresses high levels (Fig. 3.9B). Compared to HeLa HA-H3.Y cells, the amount of endogenous H3.X+Y mRNA in these U2OS cells is more than 40-fold higher. This suggests that the induction of endogenous H3.Y expression is an all or nothing reaction, meaning that when the cell receives a certain signal or the threshold of an unknown factor is reached, H3.Y is expressed in massive amounts. The discrepancy in expression levels also explains the shortcoming of HeLa HA-H3.Y cells as a model system for H3.Y function, underlining the importance of identifying the main physiological trigger of H3.Y expression for future functional studies.

## 4.6 H3.Y influences gene expression and cell growth

To address the question of H3.Y's function, global transcriptome analyses have been performed, using U2OS cells depleted of H3.Y alone or in combination with H3.X. Some hundred genes were de-regulated after both RNAi knockdowns, implying an influence of H3.Y on gene expression. Whether this influence is direct or indirect will have to be investigated in future studies, generating binding profiles of H3.Y using ChIP-chip or ChIP-seq. Interestingly, more genes were down- rather than up-regulated, arguing for a role of H3.Y in the transcriptional activation of a subset of genes. In agreement with these results, H3.Y is primarily found in euchromatic regions (Fig. 3.9F). Most of the down-regulated genes are implicated in regulating the cell cycle and the structure of chromatin, matching the reported growth defect in U2OS cells with reduced levels of H3.Y (Fig. 3.19A). Surprisingly, although only less than 0.1% of U2OS cells express H3.Y under normal growth conditions (Figs. 3.9B and 3.10), a strong and general growth defect is observed after H3.Y knockdown in these cells. It is therefore possible that all U2OS cells express H3.Y at a basal level (below the detection limit of our tools) that is crucial for the progression through the cell cycle. In line with this hypothesis, knockdown of H3.Y in HeLa cells, where no H3.Y mRNA has been detected (Fig. 3.3A), also strongly impairs cell growth (Fig. 3.19B). Recently, a similar phenotype has been reported for the linker histone variant H1.2. RNAi depletion of this variant leads to a de-regulation of ~2% of genes genome-wide, with most of them being down-regulated. Furthermore, the

lack of H1.2 causes a G1 arrest and expression changes in cell cycle-related genes (Sancho et al., 2008). This supports the idea of histone variants as important regulators of cell cycle progression and suggests that the stress-related appearance of H3.Y expressing U2OS cells might be caused by continued cell proliferation or the prevention of cell death.

Unlike the strong and cell line independent effect of H3.Y depletion on cell proliferation, the phenotypes of H3.X knockdown, alone or together with H3.Y, seem to depend on cellular background (Fig. 3.19). In U2OS cells, combined knockdown of H3.X and H3.Y has a milder effect on cell growth than H3.Y knockdown alone, whereas in HeLa cells the growth defect is almost identical in both cases. Moreover, knockdown of H3.X has hardly any effect on HeLa cells, but U2OS cells are affected even more than after H3.X+Y depletion. Speculating, this could mean that H3.X and H3.Y are connected by some sort of regulatory feedback mechanism, which would also explain why H3.Y mRNA levels are reproducibly increased after knockdown of H3.X (Fig. 3.19A, right). HeLa cells might lack this regulation due to a lack of H3.X.

It will be interesting to see what future studies, investigating the regulatory network of H3.X and H3.Y, their role in cell proliferation, and in a subpopulation of neurons in the human hippocampus, will reveal about the endogenous function(s) of these novel H3 variants.

## 4.7 Outlook

### 4.7.1 Expression of endogenous H3.X and H3.Y

#### 4.7.1.1 Trigger of H3.X and H3.Y expression in U2OS cells

In this work it could be shown that the number of U2OS cells expressing endogenous H3.Y (and H3.X) can be increased by nutritional and proliferative stress. However, all attempts to identify the actual component causing this effect under the described conditions, have failed so far. To get a better starting material for functional assays and to learn more about the expression of H3.X and H3.Y, potential candidates, such as signaling molecules or reactive oxygen species, will be tested for their ability to trigger H3.Y (and H3.X) expression.

#### 4.7.1.2 H3.X and H3.Y promoter activity and regulation

A second approach to learn more about the endogenous expression of H3.X and H3.Y, possibly giving some indications about the nature of the factor triggering expression, is the analysis of the respective promoter sequences. Bioinformatic analysis of 1000 bp upstream of the ATG

using MatInspector (Genomatix Software GmbH) revealed a multitude of potential transcription factor binding sites, many of them also implicated in different types of cellular stress. To shed light on the regulation of endogenous H3.X and H3.Y expression, activity of these promoters and truncated versions of them will be assessed using a GFP-reporter system on an episomal vector. Promoter regions of interest will substitute the SV40 promoter of EBO-Sfi EGFP (SVG) thereby driving GFP expression when the promoter is active (Hake et al., 2003). To control for the presence of the promoter in the cell, an additional *DsRed2* gene (Clontech) with a separate promoter will be cloned into the vector. SVG will serve as positive and SVG without any promoter as negative control.

#### **4.7.1.3 H3.X and H3.Y expression in human tissues**

Given that *H3.X* and *H3.Y* genes are only present in primates, H3.X/Y proteins are expressed in a sub-population of neurons in the human hippocampus and the major function of this brain region is the formation of long-term memories and the process of learning (Lagali et al., 2010), it is tempting to speculate that these novel variants play an important role in the primate brain. In order to learn more about this interesting possibility, H3.X and H3.Y mRNA and protein expression will be analyzed by *in situ* hybridization and immunohistochemistry in samples of different human brain areas. Since our group is lacking the expertise to identify structures and cell types specific for certain brain regions and we also do not have access to human brain samples, a collaboration with a neurobiology group will have to be established for this part of the project. In addition to different brain regions, H3.X and H3.Y mRNA has also been detected in several normal and especially malignant human tissues. Therefore, their expression in human tumors and corresponding normal tissues will be investigated. It will be interesting to see, whether H3.X and/or H3.Y expression plays a role in the development of cancer in certain human organs.

#### **4.7.1.4 H3.X and H3.Y expression during cell differentiation**

Since novel histone variants show an effect on proliferation, it seems reasonable to think that they might also play a role in differentiation. However, because of their primate-specific appearance, it is not possible to use mouse embryonic stem (ES) cells for these assays and human ES cells are difficult to work with in Germany due to legal restrictions. An elegant way to circumvent these problems is the expression of Oct3/4, Sox2, c-Myc, and Klf4 in somatic cells, generating so-called induced pluripotent stem (iPS) cells. These cells behave like ES

cells, show all the specific features of ES cells and can differentiate into different lineages. First established for mouse embryonic or adult fibroblasts (Takahashi and Yamanaka, 2006; Wernig et al., 2007), this approach also works with human somatic cells (Takahashi et al., 2007; Yu et al., 2007). Using this fascinating tool, it will be possible to follow H3.X and H3.Y expression during differentiation of human cells.

#### **4.7.2 *In vivo* function(s) of H3.X and H3.Y**

##### **4.7.2.1 Determination of H3.X/Y protein localization**

A first step towards a deeper understanding of H3.X and H3.Y function is the high-resolution mapping of their localization on chromatin. To this end, DNA, isolated from bound material after  $\alpha$ HA-IP of mononucleosomes from HeLa HA-H3.X and -H3.Y cells (see Fig. 3.6), will be subjected to high throughput sequencing, giving an initial idea about the genetic elements, H3.X/Y proteins are associated with. After having established a ChIP protocol working with  $\alpha$ H3.X/Y antibody, the localization of endogenous H3.X/Y proteins in U2OS cells will be mapped using ChIP-chip.

##### **4.7.2.2 Identification of H3.X and H3.Y chaperone(s)**

Knowing where H3.X/Y proteins are localized leads to the question of how they are deposited. Judging from the sequence and what is known about mammalian H3 variant deposition, H3.X and H3.Y could be incorporated into chromatin by HIRA and/or Daxx (Tagami et al., 2004; Lewis et al., 2010). However, as this is pure speculation, it will be interesting to identify the chaperone(s) specific for H3.X and H3.Y protein. Following the procedure successfully used for identification of the H3.1- and H3.3-specific chaperones CAF-1 and HIRA, respectively (Tagami et al., 2004), both novel variants will be expressed with C-terminal FLAG- and HA- or GFP-tags in HeLa cells, tagged proteins will be pulled down from cytoplasmic and nuclear extracts together with associated (chaperone) complexes, which can subsequently be identified using mass spectrometry.

##### **4.7.2.3 Replacement of *S. cerevisiae* H3 with H3.X and H3.Y**

*S. cerevisiae* has two loci encoding for H3 and H4, each containing one *H3* (*HHT*) and one *H4* (*HHF*) gene. The genes at each locus are divergently transcribed and give rise to identical

proteins (Smith and Andrésson, 1983). We have access to strain WZY42, which has both endogenous loci disrupted and only one functional copy of the endogenous *HHT2-HHF2* locus on a plasmid also encoding the *URA3* marker gene (Weber et al., 2004). This strain allows the exchange of the *S. cerevisiae* H3 with different human H3 variants, to study their intrinsic properties. On plasmid pNOY439 (Keener et al., 1997), which carries the *HHT2-HHF2* locus with an N-terminal Myc-tag upstream of the *H3* gene and a *TRP* marker gene, the yeast *H3* gene has been replaced by human *H3.1*, *H3.3*, *H3.X* and *H3.Y* coding sequences, respectively. WZY42 will now be transformed with human H3 encoding plasmids and the plasmid encoding yeast H3 will be removed by selection on 5-fluorouracil (FOA) containing plates. A first attempt to generate these strains has failed, suggesting that yeast cells are severely affected by the exchange of endogenous H3 with human variants. This is particularly interesting as point mutations of most residues, even conserved and modifiable amino acids, do not impair viability (Nakanishi et al., 2008). It will also be interesting to see, if cells can cope better with human H3.3 than with the other variants, which would be expected as the yeast H3 constitutes an H3.3-like protein.

#### 4.7.2.4 Effects of H3.X and H3.Y on cell cycle progression

Microarray analyses and growth curves of U2OS cells with reduced levels of H3.X, H3.Y or H3.X+Y point towards a role of H3.X and H3.Y in cell cycle progression. To determine where in this process novel H3 variants function, repeated and careful FACS analysis of the cell cycle profile in H3.X/Y knockdown cells will be necessary. As effects on the cell cycle profile are usually quite small and biological fluctuations rather pronounced, a well-founded statistical analysis will have to be deployed to make a statement about this issue. In addition, cell lines, expressing HA-H3.Y resistant to H3.Y- or H3.Y+Y-siRNAs, could be established to verify specificity of observed effects in rescue experiments.

#### 4.7.3 *In vitro* characterization of H3.X and H3.Y

In parallel to the described experiments aiming to elucidate the function of H3.X and H3.Y *in vivo*, additional information can be acquired by characterizing the biochemical properties of these proteins. For this approach, both proteins have been cloned in vector pET21a(+) (Novagen) for recombinant expression in BL21-CodonPlus (DE3)-RIL (Stratagene) bacteria. Proteins will be expressed, purified and octamers of H3.X or H3.Y together with canonical H2A, H2B and H4 will be assembled. With these octamers, chromatin will be reconstituted

using a 25- or 12-mer of the 601 nucleosome positioning sequence (Lowary and Widom, 1998). This highly "variant pure" substrate can subsequently be used for various assays to determine the intrinsic stability, accessibility and behavior of H3.X- and H3.Y-containing chromatin fibers.

# Abbreviations

$\alpha$	Anti
aa	Amino acid
AOTF	Acousto Optic Tunable Filter
Bbd	Barr-body deficient
BMP4	Bone morphogenetic protein 4
BSA	Bovine serum albumin
CATD	Centromere targeting domain of CENP-A
CenH3	Centromere-specific histone H3
ChIP	Chromatin immunoprecipitation
DAPI	4',6-diamidino-2-phenylindole
DG	Dentate gyrus
DKK1	Dickkopf 1
DMEM	Dulbecco's Modified Eagle Medium
DMSO	Dimethylsulfoxide
Dnmt	DNA methyltransferase
3D-SIM	3-dimensional structured illumination microscopy
DSB	Double strand break
ELISA	Enzyme-linked immunosorbent assay
ES	Embryonic stem
FACS	Fluorescence-activated cell sorting
FCS	Fetal calf serum
FOA	5-fluorouracil
4HB	Four helix bundle
FRAP	Fluorescence recovery after photobleaching
GAS1	Growth arrest specific protein 1
GFAP	Glial fibrillary acidic protein
GO	Gene ontology
HEPES	2-(4-(2-Hydroxyethyl)- 1-piperazinyl)-ethansulfonsäure
HFD	Histone-fold domain
HIRIP3	HIRA interacting protein 3
HJURP	Holliday junction-recognizing protein
HRP	Horseradish peroxidase
IF	Immunofluorescence
IGFBP3	Insulin-like growth factor binding protein 1
IH	Immunohistochemistry
IP	Immunoprecipitation

---

iPS	Induced pluripotent stem
IPTG	Isopropyl $\beta$ -D-1-Thiogalactopyranoside
l <sub>fd</sub> r	Local false discovery rate
MNase	Micrococcal nuclease
MS	Mass spectrometry
ND	Not determined
NeuN	Neuronal nuclei
ncRNAs	non-coding RNAs
no RevT	cDNA samples without reverse transcriptase
ON	Overnight
OVA	Ovalbumin
PAGE	Polyacrylamide gel electrophoresis
PBS	Phosphate buffered saline
P/S	Penicillin/Streptomycin
PTM	Posttranslational modification
qPCR	Quantitative PCR
RD	Replication dependent
RI	Replication independent
RITS	RNA-induced initiation of transcriptional gene silencing
RP-HPLC	Reversed phase-high performance liquid chromatography
RNAi	RNA interference
RT	Room temperature
S	Starvation
SDS	Sodium dodecyl sulfate
SEM	Standard error of the mean
siRNA	Short interfering RNA
SLBP	Stem loop binding protein
SO	Starvation and overgrowth
SPHK1	Sphingosine kinase 1
TBS	Tris buffered saline
TFA	Trifluoroacetic acid
TFBS	Transcription factor binding sites
TG	Throughout genome
TGF $\beta$	Transforming growth factor $\beta$
TGFBR	TGF $\beta$ receptor
UTR	Untranslated region
WB	Western blot
Xi	Inactive X chromosome

## Oligonucleotides for qPCR (continued)

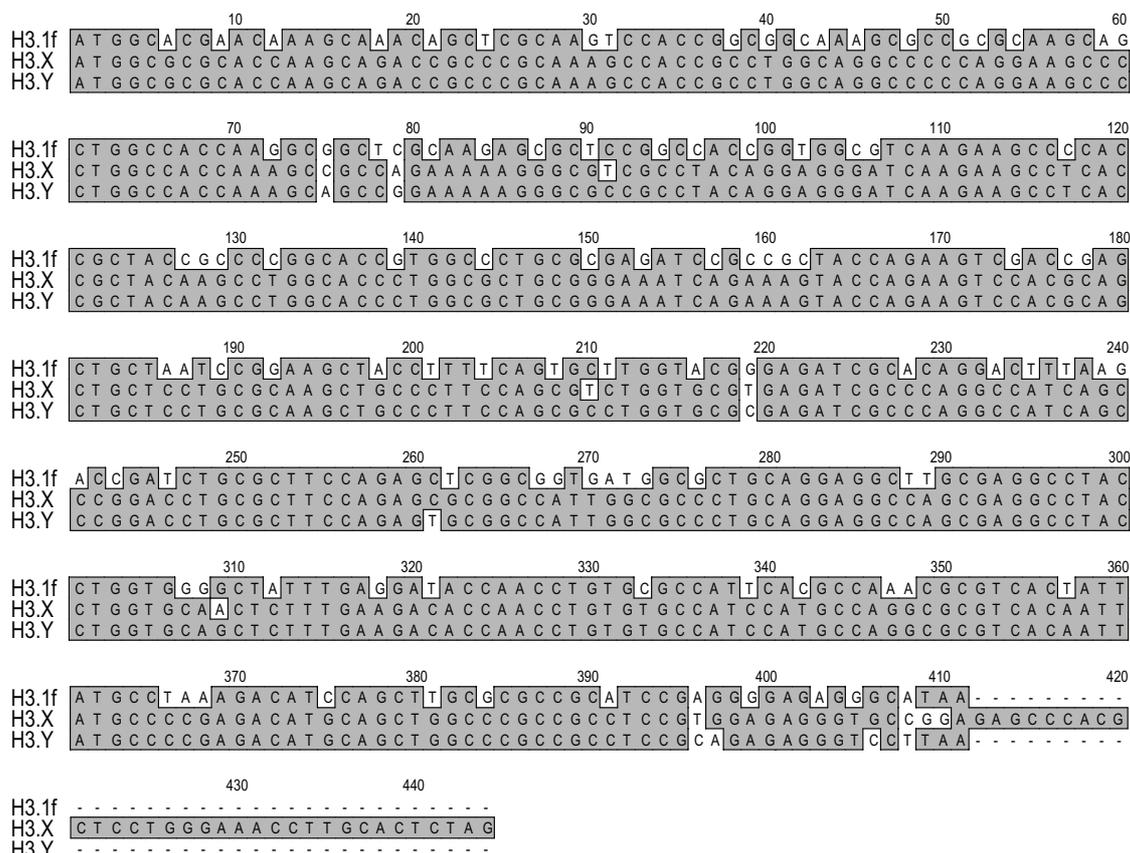

Name	Sequence	Description
NR2F1 FWD	5' TACGTGAGGAGCCAGTACCC	target genes which show a significant change in expression levels after stable expression of HA-H3.Y
NR2F1 REV	5' CCTACCAAACGGACGAAGAA	
BMP4 FWD	5' GACTTCGAGGCGACACTTCT	
BMP4 REV	5' GCTGTGGATCTGCTCTTCCT	
TGFBR2 FWD	5' GACTGAGTGCTGGGACCAC	
TGFBR2 REV	5' GGAGCCGTCTTCAGGAATCT	
SMAD6 FWD	5' TCCCTACTCTCGGCTGTCTC	
SMAD6 REV	5' GAGAATTCACCCGGAGCA	
DKK1 FWD	5' CATCAGACTGTGCCTCAGGA	
DKK1 REV	5' CCACAGTAACAACGCTGGAA	
IGFBP3 FWD	5' GGTGTCTGATCCCAAGTTCC	
IGFBP3 REV	5' CGGAGGAGAAGTTCTGGGTA	
GAS1 FWD	5' TGAGCCGCTACCTGACCTAC	
GAS1 REV	5' ACACGCAGTCGTTGAGCA	
SPHK1 FWD	5' TGAGCAGGTCACCAATGAAG	
SPHK1 REV	5' GGCTGAGCACAGAGAAGAGG	

Table A.2. Oligonucleotides for cloning

Name	Sequence	Description
H3.X+Y EcoRI FWD	5' GGAATTCAGGCAATCGCTGCG	cloning of H3.X and H3.Y cDNA into pIRES HA Neo
H3.X BamHI REV	CGCACCAAGCAGACCCG	
H3.Y BamHI REV	5' CGGGATCCCTAGAGTGCAAGG TTTCCCA	
H3.X+Y HindIII FWD	5' GAGGATAAGCTTCAGCGCGCA	cloning of H3.X and H3.Y cDNA into pEGFP-C1
H3.X SacII REV	CCAAGCAG	
H3.Y SacII REV	5' GATAATCCGCGGCTAGAGTGC AAGGTTTCCC	
H3.X+Y NdeI FWD	5' GGAATTCATATGATGGCGCG	cloning of H3.X and H3.Y cDNA into pET-21a(+)
H3.X XhoI REV	CACCAAGCAGAC	
H3.Y XhoI REV	5' CCGCTCGAGCTAGAGTGCAAG GTTTCCAG	
H3.1+2 HindIII FWD	5' GAGGATAAGCTTCAGCGCGTA	cloning of H3.1, H3.2 and H3.3 cDNA into pEGFP-C1
H3.1+2 SacII REV	CTAAGCAGACGG	
H3.3 HindIII FWD	5' GATAATCCGCGGTCACGCCCT	
H3.3 SacII REV	CTCCCCAC	
H3.X+Y siRNA mut FWD	5' GAGGATAAGCTTCAGCCCGAA	site-directed mutagenesis of siRNA-target sequences in H3.Y
H3.X+Y siRNA mut REV	CCAAGCAGACTG	
H3.Y siRNA mut FWD	5' GATAATCCGCGGTTAAGCTCT	
H3.Y siRNA mut REV	CTCTCCCCG	
H3.X+Y siRNA mut FWD	5' GGCACCCTGGCGCTGAGAGAG	site-directed mutagenesis of siRNA-target sequences in H3.Y
H3.X+Y siRNA mut REV	ATTCGGAAGTACCAGAAGTCC	
H3.Y siRNA mut FWD	5' GGACTTCTGGTACTTCCGAAT	
H3.Y siRNA mut REV	CTCTCTCAGCGCCAGGGTGCC	
H3.Y siRNA mut FWD	5' CTGGCCCCGCCCTCAGACGC	site-directed mutagenesis of siRNA-target sequences in H3.Y
H3.Y siRNA mut REV	GAAGGACCTTAAGGATCCACTAG	
H3.Y siRNA mut FWD	5' CTAGTGGATCCTTAAGGTCCT	site-directed mutagenesis of siRNA-target sequences in H3.Y
H3.Y siRNA mut REV	TCGCGTCTGAGCGCGGGCCAG	

**Table A.3.** Oligonucleotides for RNAi

Name	Sequence	Description
luciferase sense	5' CUUACGCUGAGUACUUCGAdTdT	control siRNA
luciferase antisense	5' UCGAAGUACUCAGCGUAAGdTdT	
H3.X sense	5' CACCAAAGCCGCCAGAAAAdTdT	siRNA targets specifically H3.X
H3.X antisense	5' UUUUCUGGCGGCCUUUGGUGdTdT	
H3.Y sense	5' CCGCAGAGAGGGUCCUUAAdTdT	siRNA targets specifically H3.Y
H3.Y antisense	5' UUAAGGACCCUCUCUGCGGdTdT	
H3.X+Y sense	5' GCGGGAAAUCAGAAAAGUACdTdT	siRNA targets H3.X and H3.Y
H3.X+Y antisense	5' GUACUUUCUGAUUUCCCGCdTdT	

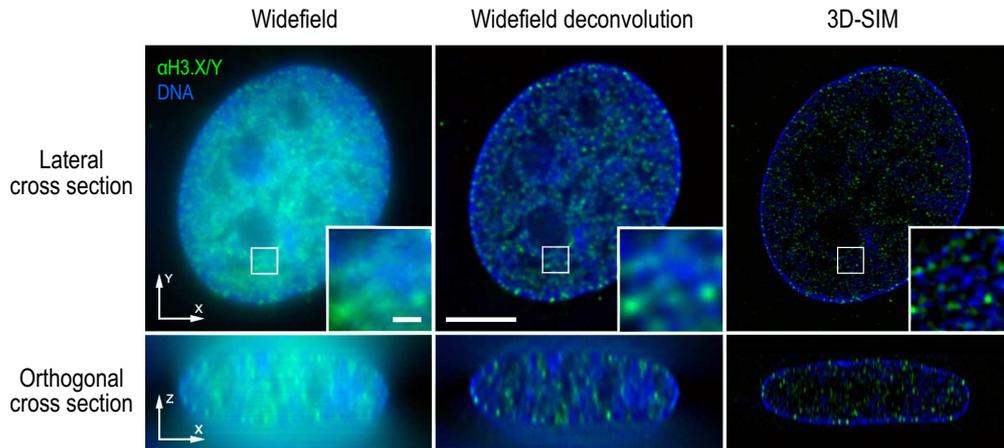

**Figure A.1.** Nucleotide sequence alignment of human *H3.X* and *H3.Y* with *H3.1*.

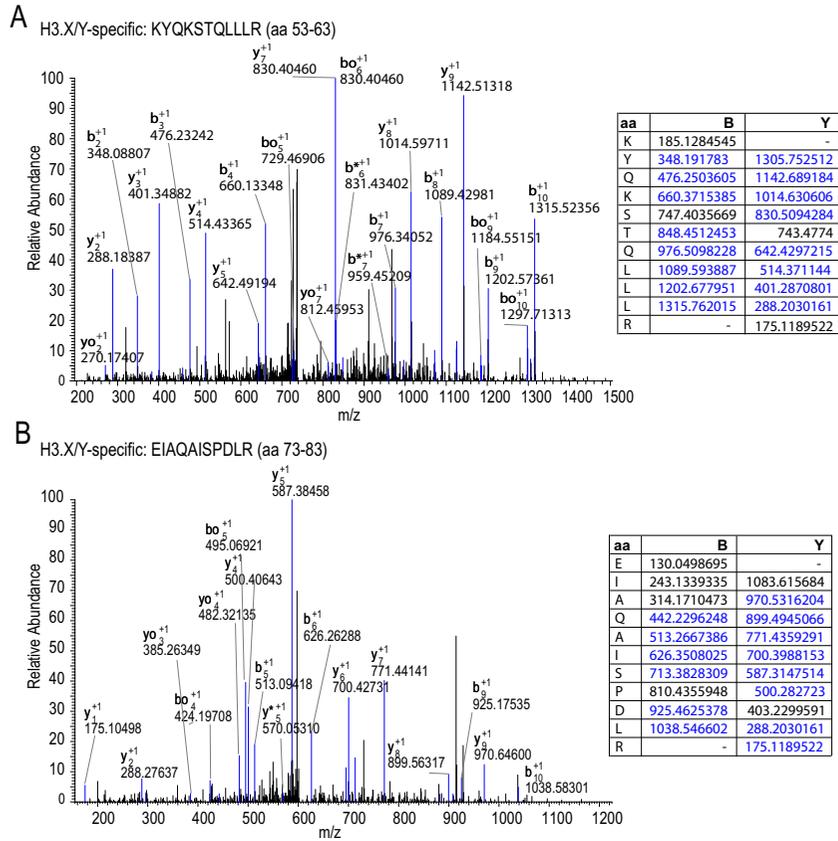

Alignment of coding nucleotide sequences of human *H3.1f* (NM\_003533), *H3.X* (LOC340096) and *H3.Y* (LOC391769) genes. Identical nucleotides are highlighted in dark gray and changes are set apart on a white background.

**Figure A.2. Amino acid sequence alignment of H3.X and H3.Y from different primate species.** Alignment of human (*H. sapiens*), chimpanzee (*P. troglodytes*) and macaque (*M. mulatta*) H3.X and H3.Y protein sequences. Sequence similarity is encoded by background color: identical aa = dark gray, similar aa = light gray, different aa = white. Note that the macaque H3.X ends, like H3.Y, after aa 135 (asterisk indicates stop codon) but following amino acids would code for the extra C-terminus of H3.X.

**Figure A.3. Comparison of different microscopy techniques.** Lateral (top) and orthogonal (bottom) sections of U2OS cells, co-stained with  $\alpha$ H3.X/Y (green) and DAPI (DNA, blue), are depicted. Images were acquired using a widefield (left) or an OMX DeltaVision (right) microscope. A deconvolved version of the left image is shown in the middle. Scale bar equals 5  $\mu$ m. Insets show enlargements of boxed areas with scale bar equaling 0.5  $\mu$ m. With 3D-SIM resolution, but not with that of conventional microscopy, localization of H3.X/Y protein outside of DAPI-dense regions is visible.

**Figure A.4. MS/MS spectra of H3.X/Y- and H3.Y-specific peptides.** NanoLC-ESIMS/MS analysis of propionylated and trypsin-digested proteins in RP-HPLC fractions corresponding to region A bands from U2OS SO experiment 1 (see Fig. 3.13Cii). Depicted are MS/MS spectra of doubly charged precursor ions of peptides specific for H3.X and H3.Y ((A)  $m/z = 745.44$ , (B)  $m/z = 606.83$ ) and unmodified or acetylated H3.Y-specific peptide ((C)  $m/z = 654.90$ , (D)  $m/z = 640.88$  and (E)  $m/z = 647.90$ ). Boxes on the right show specific b and y ions after fragmentation.

**Figure A.5. GO groups significantly affected by H3.Y and H3.X+Y knockdown in U2OS cells.** Comprehensive list of GO groups comprising genes that are significantly up- (A) or down- (B) regulated after siRNA knockdown of H3.Y and H3.X+Y in U2OS cells compared to luciferase control knockdown. For number of overlapping genes see Venn diagrams in Fig. 3.18B. Size = total number of genes analyzed in this node (GO term), ExpCount = number of "responders" expected (entering the term by chance), Count = actual number of "responders" found in the node.

**Figure A.6. Alternative H3.X transcripts.**

The annotation of the *H3.X* gene locus (LOC340096) in the NCBI database has changed several times over the last years. Shown is a scheme (top) and an amino acid sequence alignment (bottom) visualizing the different predicted H3.X proteins. Note that unlike H3.X, H3.X-1 and H3.X-2 consist of several exons. Identical amino acids are depicted on a dark gray, similar amino acids on a light gray and different amino acids on a white background.

# List of Figures

1.1	Crystal structure of the nucleosome . . . . .	5
1.2	Chromatin - composition and compaction . . . . .	6
1.3	Epigenetic regulation . . . . .	8
1.4	Protein sequences of human core histone variants . . . . .	13
3.1	Amino acid sequence alignment of human histone H3 variants . . . . .	45
3.2	Phylogenetic tree of H3.X and H3.Y from different species . . . . .	46
3.3	H3.X/Y mRNA levels in different cell lines and human tissues . . . . .	47
3.4	Sub-cellular localization of HA-tagged histone H3 variants . . . . .	49
3.5	<i>In silico</i> homology models of H3.X and H3.Y protein structure . . . . .	50
3.6	Composition of H3.X and H3.Y containing nucleosomes . . . . .	51
3.7	Exchange mobility behavior of GFP-tagged H3 variants . . . . .	52
3.8	Evaluation of $\alpha$ H3.X/Y antibody specificity . . . . .	53
3.9	Endogenous H3.X/Y expression and sub-nuclear localization . . . . .	54
3.10	Test of different stress conditions as trigger for H3.X/Y expression in U2OS cells	56
3.11	Increase of H3.X/Y expressing U2OS cells by nutritional and proliferative stress	57
3.12	Evaluation of inducible endogenous H3.X and H3.Y expression . . . . .	58
3.13	Purification and identification of endogenous H3.Y protein . . . . .	59
3.14	GO enrichment analysis of de-regulated genes in HeLa HA-H3.Y cells . . . . .	61
3.15	Gene expression levels in HeLa cells stably expressing HA-tagged H3 variants	62
3.16	Influences of HA-H3.Y expression and SO treatment on gene expression . . . . .	63
3.17	Evaluation of H3.X/Y siRNA specificity . . . . .	65
3.18	mRNA expression profiling of U2OS cells after H3.Y or H3.X+Y knockdown	66
3.19	Influence of H3.X and/or H3.Y knockdown on proliferation capacity . . . . .	67
3.20	H3.X/Y expression in human brain . . . . .	68
3.21	H3.X/Y expression in primates . . . . .	70
A.1	Nucleotide sequence alignment of human <i>H3.X</i> and <i>H3.Y</i> with <i>H3.1f</i> . . . . .	III
A.2	Amino acid sequence alignment of H3.X and H3.Y from different primate species	IV
A.3	Comparison of different microscopy techniques . . . . .	IV
A.4	MS/MS spectra of H3.X/Y- and H3.Y-specific peptides . . . . .	V
A.5	GO groups significantly affected by H3.Y and H3.X+Y knockdown in U2OS cells	VI
A.6	Alternative H3.X transcripts . . . . .	VII

# List of Tables

1.1	Human core histone variants . . . . .	12
2.8	Mammalian cell lines . . . . .	28
2.9	Stably transfected mammalian cell lines . . . . .	28
A.1	Oligonucleotides for qPCR . . . . .	I
A.2	Oligonucleotides for cloning . . . . .	II
A.3	Oligonucleotides for RNAi . . . . .	III

# Curriculum vitae

Sonja M. Wiedemann

Birth name: Nieratschker  
Date of birth: March 1<sup>st</sup> 1983  
Place of birth: München

## Education

- 10/2007 - present **PhD thesis at the Ludwig-Maximilians-University of Munich, Adolf-Butenandt-Institute, Prof. Peter Becker, Group of Dr. Sandra Hake**  
Member of the International Max Planck Research School for Molecular and Cellular Life Sciences  
Project: Identification and characterization of two novel primate-specific histone H3 variants, H3.X and H3.Y
- 01/2006 - 05/2006 **Internship at the University of Michigan, Ann Arbor, MI, USA, Department of Molecular, Cellular & Developmental Biology, Laboratory of Dr. Ursula Jakob**  
Project: Oxidative stress and its implication for aging in the model organism *Caenorhabditis elegans*
- 10/2002 - 08/2007 **Studies in biochemistry at the University of Regensburg**  
Diploma thesis: Glycosylation defects and apoptosis in *Saccharomyces cerevisiae* - Identification of RPR1 and Lhp1 as new components  
Scholarships: German National Merit Foundation (Studienstiftung des deutschen Volkes), Bavarian Scholarship Programme for highly talented students (Bayerische Begabtenförderung)
- 09/1993 - 06/2002 **Secondary school: Schyren-Gymnasium Pfaffenhofen a.d. Ilm**  
Abitur
