# 1. ZUSAMMENFASSUNG

Die Landoberfläche beeinflusst das Wetter- und Klimageschehen in grundlegender Art und Weise. Der Bio-, Pedo- und Kryosphäre kommt dabei eine besondere Bedeutung als Klimatreiber zu. Durch aerodynamischen Widerstand, Albedo, Emissivität und den Austausch latenter und fühlbarer Wärme über Boden und Pflanzen steuern verschiedene Landoberflächen mit ihren jeweils unterschiedlichen charakteristischen Eigenschaften das Geschehen in der Atmosphäre maßgeblich mit. Die räumliche Heterogenität der Landoberfläche als auch die zeitliche Dynamik der auf der Landoberfläche ablaufenden Prozesse stellen eine wesentliche Herausforderung in Landoberflächenmodellen dar. Die komplexen Wechselwirkungen zwischen atmosphärischen Prozessen und solchen auf der Landoberfläche sowie damit einhergehender Rückkopplungseffekte können in Modellen nur simuliert werden, wenn ein Austausch von Energie- und Masseflüssen zwischen diesen Modellkomponenten stattfindet. Klimamodelle berücksichtigen diese wechselseitigen Beziehungen seit jeher, mit zunehmender Bedeutung und Komplexität. Hier werden die Energieflüsse der Landoberfläche in eigens dafür entwickelten Landoberflächenmodellen als sogenannte untere Randbedingung an die Atmosphäre im Klimamodell übergeben. Die Landoberfläche wird in Klimamodellen jedoch meist nur grob und stark vereinfacht berücksichtigt, um die Wechselbeziehungen zwischen Landoberfläche und Atmosphäre für bestimmte wissenschaftliche Fragestellungen hinreichend zu simulieren. Gegenwärtig werden große Anstrengungen unternommen, um Landoberflächenmodelle in Klimamodellen zu verbessern.

Hydrologische Modelle auf der anderen Seite beschreiben Landoberflächen mit einem Fokus auf hydrologische Prozesse mit hoher räumlicher Auflösung (z.B. Boden-Pflanzen Interaktionen, vertikale und horizontale Bewegung von Wasser auf der Landoberfläche und im Boden, Schnee und Eis). Dabei behandeln sie jedoch den meteorologisch-atmosphärischen Antrieb aus Klimamodellen in der Regel exogen und können daher Interaktionen und Rückkopplungseffekte zwischen der Landoberfläche und der Atmosphäre nicht berücksichtigen. Hydrologische Modelle wurden bislang erfolgreich mit Daten aus regionalen Klimamodellen angetrieben, um z.B. regionale Auswirkungen des Klimawandels auf die Hydrologie in kleinen Einzugsgebieten zu simulieren und zu erforschen. Für eine konsistente Analyse der regionalen Auswirkungen des Klimawandels müsste das hydrologische Modell

jedoch bidirektional mit dem Klimamodell gekoppelt werden, um explizit Rückkopplungen berücksichtigen zu können.

Inhalt dieser Arbeit war daher die bidirektionale Kopplung eines hydrologischen Landoberflächenmodells mit einem regionalen Klimamodell, mit der Zielsetzung die Vorteile hochauflösender hydrologischer Modelle mit der Fähigkeit von Klimamodellen, nämlich die Berücksichtigung von Wechselwirkungen und Rückkopplungen zwischen Landoberfläche und Atmosphäre, zu verbinden.

Beim Vergleich des Landoberflächenmodells NOAH, wie es aktuell im Klimamodell MM5 benutzt wird, mit dem hydrologischen Landoberflächenmodell PROMET zeigte sich, dass die selben physikalischen Prozesse in den Modellen verschieden formuliert werden. Die in PROMET implementierten Prozessbeschreibungen innerhalb des Boden-Pflanzen-Atmosphären-Kontinuums sind detaillierter, komplexer und umfangreicher als jene in NOAH. Dafür sind umfangreichere Pflanzen- und Bodenparametrisierungen notwendig, die für die Prozessbeschreibungen in den Modellen erforderlich sind. Die dafür benötigten Daten werden in PROMET aus Literatur, Messungen und Fernerkundungsdaten abgeleitet. Neben der unterschiedlichen Parametrisierung benutzen die Modelle aus den verschiedenen Disziplinen unterschiedliche räumliche und zeitliche Skalen. So rechnet PROMET mit  $1 \times 1 \text{ km}^2$  auf einer feineren räumlichen Skala als NOAH ( $45 \times 45 \text{ km}^2$ ) und kann somit die räumliche Heterogenität für das Modellgebiet in Mitteleuropa mit einer wesentlich höheren Genauigkeit darstellen. Dafür benötigt PROMET u.a. einen höheren Informationsgehalt in den Eingangsdaten (wie z.B. Landbedeckung bzw. Landnutzung, Boden, Gelände).

Um diese Informationen für das Simulationsgebiet von Zentraleuropa ( $1170 \times 1170 \text{ km}^2$ ) in hoher räumlicher Auflösung bereitstellen zu können, wurde ein neuer Landnutzungsdatensatz erzeugt. Durch die Kombination bereits existierender Landnutzungsklassifikationen, hochauflösenden MERIS-NDVI Fernerkundungsdaten und statistischen Datensätzen konnte die räumliche Heterogenität v.a. innerhalb von landwirtschaftlich bewirtschafteten Flächen verbessert werden. Daraus resultierten deutliche zeitliche und räumliche Veränderungen in der Verdunstungssimulation an der Oberen Donau, was dort schließlich zu einer Verbesserung der Wasserbilanz führte. Die Verbesserungen waren dabei vor allem auf unterschiedliche phänologische Entwicklungen von verschiedenen Ackerfrüchten zurückzuführen.

Aus den unterschiedlichen Modellkonzepten ergaben sich im Vergleich mit NOAH stark unterschiedliche Ergebnisse in der Verdunstung, die in Norditalien bis zu  $280 \text{ mm Jahr}^{-1}$  betrug. Dabei spielten die Landnutzung und insbesondere versiegelte urbane Flächen eine wesentliche Rolle, die in NOAH auf Grund der groben Auflösung im Modellgebiet nicht berücksichtigt werden. Durch deren thermodynamische und hydraulische Eigenschaften tragen versiegelte Flächen deutlich weniger zur Verdunstung bei, als z.B. mit Vegetation bewachsene Flächen, die durch Transpiration pflanzenverfügbares Wasser aus dem Boden verdunsten. Daneben führten vor allem unterschiedliche Boden- und Vegetationsparameter zu unterschiedlicher Bodenfeuchte und unterschiedlichen Verdunstungsraten.

Bidirektional gekoppelt ändert sich der Zustand der Atmosphäre von MM5 als Reaktion auf veränderte untere Randbedingungen durch den Austausch von NOAH mit PROMET. Folglich stieg z.B. die jährliche Mitteltemperatur im Modellierungsgebiet um 1 K und der Niederschlag ging um 56 mm zurück. Somit konnte gezeigt werden, dass physikalisch basierte hydrologische Modelle wie PROMET in der Lage sind, die unteren Randbedingungen für Klimamodelle in bidirektional gekoppelten Modellläufen adäquat bereitzustellen. Die daraus resultierenden Zustandsänderungen der Atmosphäre als Reaktion auf die geänderten unteren Randbedingungen sind sowohl nachvollziehbar, als auch in einer realistischen Größenordnung. Die durch PROMET induzierten Änderungen der Masse- und Energieflüsse zwischen Landoberfläche und Atmosphäre führten beim Betrachten der Verdunstung schließlich sowohl zu positiven, als auch zu negativen Rückkopplungseffekten. Die vorherrschenden hydrologischen Bedingungen bestimmten dabei das positive oder negative Vorzeichen, als auch die Stärke der Rückkopplung. In bereits trockenen Regionen in ungekoppelten Simulationen, wie z.B. in Norditalien, führte sommerliche Hitze zu einem vermehrten Austrocknen der Böden und damit zu mehr Wasserstress bei Pflanzen. Dies mündete in einen Rückgang der Verdunstung um bis zu 30 % und wiederum in eine geringere Verdunstungskühlung. Nördlich der Alpen hingegen war das Gegenteil der Fall. Hier führte ein Anstieg der Temperaturen zu überwiegend mehr Verdunstung, da der Boden hier meist noch genug pflanzenverfügbares Wasser beinhaltet.

Weitere Analysen zeigten außerdem, dass Klimamodelle wie MM5 im bidirektional gekoppelten Modus durch die genauere Repräsentation der Landoberfläche in PROMET profitieren, indem z.B. die Simulation von tageszeitlichen, monatlichen und jährlichen Temperaturverläufen im Vergleich mit Messergebnissen an der Oberen Donau verbessert wurden. Dabei konnte vor allem der Temperaturverlauf an den bisher zu kühlen, frühen

Nachmittagsstunden verbessert werden. Ein Vergleich mit Messungen zeigte zudem eine Verbesserung bei der Simulation von eintreffender Sonnenstrahlung, was darauf schließen lässt, dass Prozesse wie Wolkenbildung ebenfalls präziser abgebildet wurden. Die in Klimamodellen, vor allem in Gebieten mit starkem Relief, meist überschätzten Niederschläge, wurden deutlich reduziert, wenngleich die Unsicherheiten v.a. in der räumlichen Verteilung von simulierten Niederschlagsmengen über den Alpen auf Grund von schwierig zu simulierenden subskaligen Konvektionsprozessen in den Klimamodellen immer noch eine große Herausforderung darstellen. Durch die bidirektionale Kopplung konnten dennoch alle Terme der Wasserbilanz für das Einzugsgebiet der Oberen Donau verbessert werden.

Durch die Berücksichtigung von gegenseitigen Wechselbeziehungen und Rückkopplungen in die Simulation ist es mit dem entwickelten Ansatz möglich, nicht nur die Auswirkungen des Klimawandels auf die Hydrologie der Landoberflächen, sondern auch die hydrologischen Auswirkungen auf das Klima in Modellen besser zu erfassen. Somit ermöglicht die bidirektionale Kopplung von Landoberflächenmodellen wie PROMET mit Klimamodellen, genauere Aussagen und weitergehende Analysen als bisher über die Auswirkungen von Landoberflächenprozessen auf verschiedene Aspekte des Klimawandels sowohl in der Atmosphäre (z.B. Temperatur, Wolkenbildung, Niederschlag), als auch durch Rückkopplungen induzierte Änderungen auf der Landoberfläche selbst (z.B. Bodenfeuchte, Schnee- und Eisschmelze, Landnutzung, Verstädterung, Albedo, Verdunstung, Pflanzenwachstum, Abflussbildung, Perkolation, Permafrost).

## 2. SUMMARY

The land surface influences weather and climate in a fundamental way. The bio-, pedo- and cryosphere play a particularly important role as climate drivers. By aerodynamic resistance, albedo, emissivity, and the exchange of latent and sensible heat via soil and plants, the land surface largely controls the processes within the atmosphere. The spatial heterogeneity of land surface properties and the temporal variability of land surface processes are a major challenge in land surface models. The complex interactions between atmospheric processes and those on the land surface and concomitant feedback effects can only be allowed in simulations, if energy and mass fluxes are exchanged between these model components. Climate models have always taken into account these interrelationships with increasing importance and complexity. Here, the energy flows of the land surface are transferred to the atmosphere as the lower boundary conditions. The representation of the land surface in current climate models, however, is coarse and does not sufficiently address certain scientific questions in terms of interactions between the land surface and the atmosphere. Thus, great efforts are currently being made to improve land surface models in climate models.

In contrast to land surface representations in climate models, land surface hydrological models (LSHMs) take the land surface with a focus on hydrological processes into detailed spatial account (e.g. soil-plant interactions, vertical and lateral water flows, snow and ice). However, they usually consider the atmosphere as an exogenous driver only, thereby neglecting interactions and feedbacks between the land surface and the atmosphere. LSHMs have been driven successfully with data from regional climate models, for example in order to simulate regional impacts of climate change on the hydrology in small catchment areas. A consistent analysis of the regional impacts of climate change, would request to couple the hydrological model bi-directionally with the climate model to explicitly take into account feedback effects.

Therefore, the purpose of this thesis is a bi-directional (two-way) coupling of a LSHM with a regional climate model (RCM), with the aim to combine the advantages of high resolution LSHMs with the ability to simulate land-atmosphere interactions and feedbacks with RCMs.

A comparison of the land surface model NOAH, as it is currently used within the climate model MM5, with the land surface hydrological model PROMET, showed that the same physical processes are formulated differently in the models. Thus, the process descriptions as

formulated in PROMET are more detailed, complex and more comprehensive than in NOAH. Therefore, more detailed plant and soil parameterizations are needed, which are necessary for the process descriptions in the models. In PROMET, the required data are derived from literature, measurements and remote sensing data. Besides the different parameterizations, the models from different disciplines are using different spatial and temporal scale. PROMET ( $1 \times 1 \text{ km}^2$ ) simulates on a finer spatial scale than NOAH ( $45 \times 45 \text{ km}^2$ ) and, thus, the spatial heterogeneity for the model area in Central Europe is at higher accuracy. This requires greater information content in the input data of PROMET (land use, soil, terrain).

To provide this information for the modelling domain of Central Europe ( $1170 \times 1170 \text{ km}^2$ ) with high spatial resolution, a new land use/cover dataset was compiled. By combining existing land use/cover datasets, high resolution MERIS-NDVI remote sensing and statistical data, the spatial heterogeneity could be improved, especially for different types of crops within arable land. Consequently, the spatial and temporal behaviour of simulated evapotranspiration resulted in an improved simulation of the water balance for the Upper Danube. The improvements were mainly due to differences in phenological development of different agricultural crops.

The different model concepts resulted in greatly different results in simulated evapotranspiration when compared to NOAH. The difference was up to  $280 \text{ mm year}^{-1}$  in northern Italy. Thereby, the land-use and particularly sealed urban areas played an important role, which are not included in the model domain in NOAH due to the coarse spatial resolution. Due to their thermodynamic and hydraulic properties, these areas contribute substantially less to evapotranspiration in contrast to vegetated surfaces that transpire available soil water. Additionally, different soil and vegetation parameters resulted in different soil moisture and different evapotranspiration rates.

Bi-directionally coupled, the state of the atmosphere of MM5 responses to changes due to the changed lower boundary conditions by the exchange of NOAH with PROMET. Consequently, the annual mean near surface air temperature in the modelling domain increased around 1K and precipitation decreased by 56 mm. Thus, it could be shown that physically-based models such as PROMET are able to provide the lower boundary conditions for climate models in bi-directionally coupled model runs in an adequate way. The resulting changes within the atmosphere in response to the modified lower boundary conditions are both understandable and in a realistic order of magnitude. PROMET induced changes in land-atmosphere mass and energy flows finally led to both positive and negative feedback effects

on the evaporation. Thereby, the prevailing hydrological conditions determined the positive or negative signs, as well as the strength of the feedback. In regions that were already dry in uncoupled simulations, e.g. in Northern Italy, summer heat resulted in even more drying of the soil and, thus, to greater water stress in plants, which resulted in lower evaporation rates by up to 30 % and in turn in less evaporative cooling. North of the Alps, however, the opposite was the case. Here, a rise in temperatures predominantly increased evaporation because soil water was still available for plants.

Further analysis also showed that climate models such as MM5 benefit in the bi-directionally coupled mode from the more detailed representation of the land surface in PROMET. As an example, the simulation of the diurnal, monthly and annual cycle of the near surface air temperature could be improved when compared with measurements for the Upper Danube. Thereby, particularly a cold bias in the simulated daily maximum temperatures in the early afternoon hours could be improved. In comparison to measurements, the amount of incoming solar radiation has also been improved, which suggests that processes such as cloud formation have also been reproduced more accurately. The climate models generally overestimated precipitation, especially in mountainous areas. However, precipitation amounts could be reduced, although uncertainties in alpine precipitation still remain high due to subscale convection is still challenging to simulate in climate models. The bi-directional coupling could finally improve all terms of the water balance for the catchment area of the Upper Danube.

By incorporating feedbacks into the simulation, it is therefore possible to detect not only the effects of climate change on the land surface hydrology, but also the hydrological impact on the climate. Thus enabling the bidirectional coupling of land surface models such as PROMET with climate models, allows more precise statements and further analysis of the impact of land surface processes on different aspects of climate change both in the atmosphere (e.g. temperature, cloud formation, precipitation), as well as by feedback-induced changes upon the land surface itself (e.g. soil moisture, snow and ice melt, land use, urbanization, albedo, evapotranspiration, plant growth, runoff, percolation, permafrost).

### 3. ACKNOWLEDGEMENTS

The work was carried out at the Ludwig-Maximilians-University in Munich at the chair of Geography and Remote Sensing at the Department of Geography. As the head of the chair and my supervisor, Prof. Dr. Wolfram Mauser deserves my first and most sincere thanks for giving me the opportunity to work on this thesis and providing me with excellent advises, professional working conditions and the needed computational resources for the performed simulations. I always appreciated his valuable review and his open, friendly and direct mind. Already as a student, he fascinated me for the broad field and modern opportunities of geographical topics. Also, I want to express my gratefulness to Prof. Dr. Ralf Ludwig for the review of this thesis. Further, I want to thank all the employees of the chair and all my dear colleagues.

This interdisciplinary study could not have been achieved without the background of the GLOWA-Danube project. The financial funding of GLOWA-Danube by the German ministry of Education and Research (BMBF) is gratefully acknowledged. Thereby, I want to thank all the former GLOWA- colleagues, especially Dr. Markus Muerth, Dr. Daniel Waldmann, Dr. Monika Prasch and Andrea Reiter.

My special thanks go to Dr. Thomas Marke and Dr. Tobias Hank for their valuable expertise and cooperation. Many thanks also go to the meteorologists Prof. Dr. Günther Zängl, Andreas Pfeiffer and Dr. Clemens Wastl for the great collaboration within the GLOWA-Danube project and, in regards of this study, their expert meteorological knowledge concerning the regional climate model MM5.

Further, I would like to thank all my fellow Ph.D. students and roommates for the valuable discussions, the cooperation, their technical support and the nice atmosphere. Thus, my special thanks go to Florian Schlenz, Thomas Sailer, Tamara Avellan, Birgitta Putzenlechner, Shrabana Datta, and all the others not named here.

It is my special concern to thank my band A HOME. A HEART. WHATEVER. and namely the band members Dr. Marcus Schreiner and Tobias Mecklinger for the great and intense time we have already spent together. The rehearsals and gigs were always the best choice to clear my mind from work, relax, refresh and re-energize.

Finally, I want to thank my parents, sisters, brothers, nieces and nephews, my friends and particularly Emily for their support and motivation, and for having the best and most wonderful friends one can have.

---

## 7. INTRODUCTION

The climate system consists of the earth's atmosphere, oceans and the terrestrial components including the biosphere, the hydrosphere, the soils, the cryosphere and the orography (Figure 7.1). These components are all linked with each other by fluxes of mass, heat and momentum. Thereby, physical, chemical and biological interactions occur on a wide range of spatial and temporal scales, making the climate system extremely complex (Bridgman and Oliver, 2006). Initial perturbations within one component lead to responses in other components. Resulting feedback mechanisms may amplify or reduce changes in response to the initial perturbation and hence are very important aspects in the climate system (IPCC, 2001). Thus, for modelling the climate adequately and provide climate scenarios, all components must be interactively connected and represented in a realistic way (IPCC, 2001). Therefore, climate models must be able to represent the land surface energy and water balance, the spatial heterogeneity of the land surface, the temporal variability of its complex interdependent processes, human activities and natural processes that impact upon the land surface, and the surface-atmosphere interactions (Pitman, 2003). Nevertheless, land-atmosphere interactions are still one of the key sources of uncertainties in current climate scenarios and simulations (IPCC, 2007a).

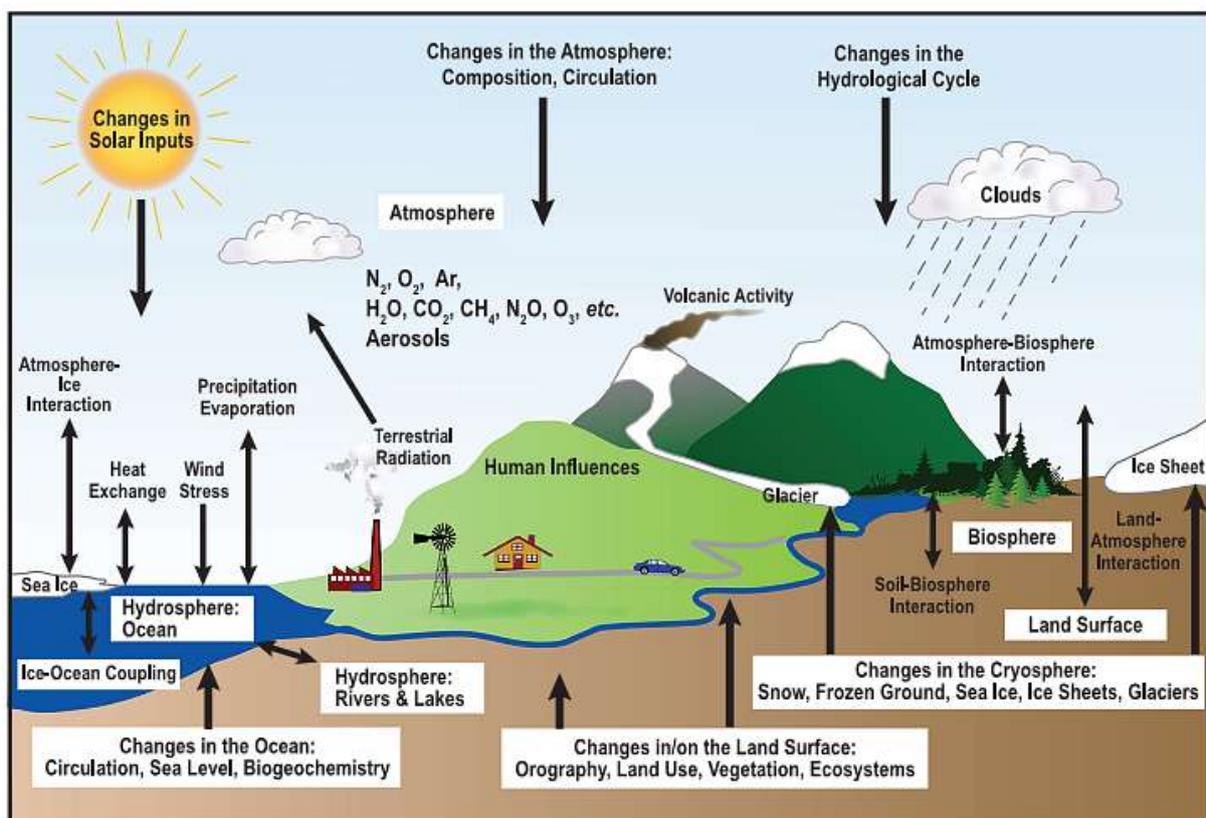

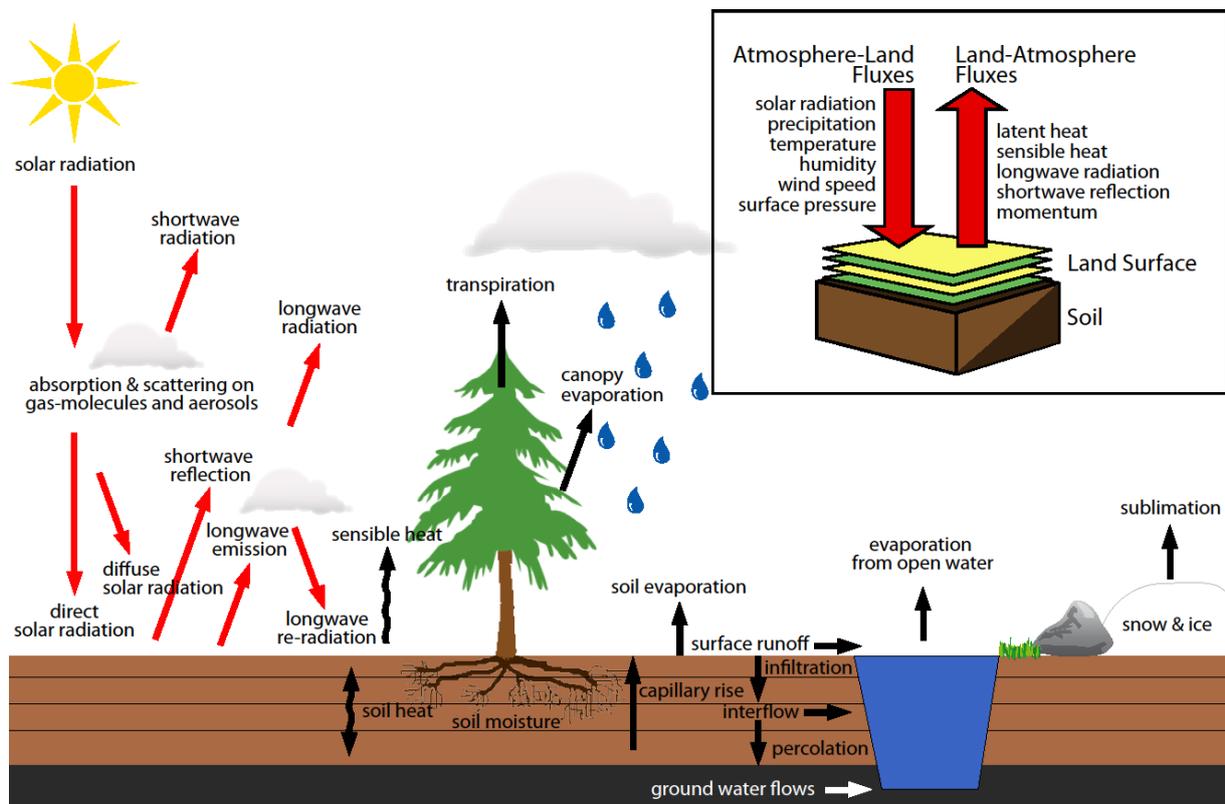

Figure 7.1: The climate system (IPCC, 2001).

## 7.1. Interactions

**Figure 7.1.1: Energy balance at the land surface, divided into the radiation balance (red arrows), the water balance (black, straight arrows) and the heat fluxes (black, curved arrows).**

The components of the climate system are not closed systems in a physical sense, since matter and heat is exchanged with its surroundings through atmosphere-land and land-atmosphere interactions. Thereby, the interactions between the components form inter-componential balances (see Figure 7.1.1). The key equations that represent the role of the land surface in climate are the energy balance (Eq. 2) and the surface water balance (Eq. 3) (Pitman, 2003). Besides, the surface influences momentum exchange and, biogeochemical exchange, such as the carbon balance.

The Earth's only significant energy source is the exogenous solar radiation. On its way to the land surface, it is attenuated on gas-molecules (e.g.  $N_2$ ,  $O_2$ ,  $H_2O$  vapor,  $CO_2$ ,  $CH_4$ , and  $O_3$ ) and aerosols in the Earth's atmosphere by processes of scattering and absorption (Monteith and Unsworth, 2008). Thus, the land surface receives the transmitted direct and forward scattered diffuse short-wave solar radiation.

The incoming solar radiation ( $S \downarrow$ ) at the land surface is further reflected or absorbed, depending on the surface's albedo ( $\alpha$ ). Albedo naturally changes with solar insolation angle, vegetation phenology, rain and snowfall, but can also be changed directly by natural and

human induced land cover change or indirectly, e.g., by fertilizing effects on vegetation. Typical albedo values for different land surfaces are shown in Table 7.1.1.

**Table 7.1.1: Typical Albedo values for different land surfaces (Marshall and Plumb, 2008).**

Land surface	Albedo [%]
Forest	6-18
City	14-18
Grass	7-25
Ice	20-77
Snow (old to fresh)	40-95

The land surface continuously emits long-wave radiation ( $L \uparrow$ ) following the Stefan-Boltzmann-law, depending on the characterized emissivity and the temperature of a specific land surface type. The emitted long-wave radiation is partly absorbed by atmospheric gases that in turn re-radiate from the atmosphere to the land surface which is known as the greenhouse effect ( $L \downarrow$ ) (Marshall and Plumb, 2008). Eventually, the radiation balance (Eq. 1) from short- and longwave radiation results in the net radiation ( $R_n$ ), which describes the total amount of energy that is available at the land surface.

$$R_n = S \downarrow (1 - \alpha) + L \downarrow - L \uparrow \quad (\text{Eq. 1})$$

The available net radiation is partitioned into sensible ( $H$ ), latent ( $LE$ ), and the soil or ground heat flux ( $G$ ), as described in the land surface energy balance (Eq.2).

$$R_n = LE + H + G \quad (\text{Eq. 2})$$

Consequently, a decrease of latent heat will automatically result in an increase of sensible heat if net-radiation and soil heat flux remain constant. The distribution of the net radiation into latent, sensible and soil heat is driven by complex inter-dependent processes within the soil-plant-atmosphere continuum. Thereby, soil heat transfer is largely determined by the current soil moisture and the thermal properties of the soil matrix (Muerth and Mauser, 2012). The water pathway via the soil through the roots into the leaf and passing via the stomata into the laminar and finally the turbulent atmosphere is driven by the potential difference of water vapour pressure between the surface and the atmosphere. These processes occur on a wide range of temporal scales ranging from minutes (canopy resistance), weeks (vegetation phenology) to years (vegetation dynamics). The flux of momentum itself is not affecting the

surface energy balance, but it is of importance because the atmospheric resistance to heat and mass transport is closely related to this flux (Berge, 1990).

Atmospheric processes are largely sensitive to the partitioning of net radiation into latent and sensible heat. More latent heat contributes to more water vapour in the atmosphere and tends towards increasing cloudiness and precipitation, whereas increased sensible heat tends to heat the planetary boundary layer and increase convection (Kabat et al., 2004; Pitman, 2003).

The atmosphere is the most unstable and rapidly changing fluid part of the climate system. Its turbulent moving air masses within the planetary boundary layer in the lower part of the atmosphere transport the received heat and mass from the land surface vertically and horizontally (Berge, 1990). Thereby, the height of the boundary layer depends upon the strength of the surface-generated mixing. When the Earth's surface is heated by the Sun, thermal heat is transferred upwards (convection). This enables the boundary layer to extend its height up to 2 km, while by night, when atmosphere cools down slower than the surface, there is a downward transfer of heat and the height of the boundary layer shrinks to less than 100 m (Oke, 1987).

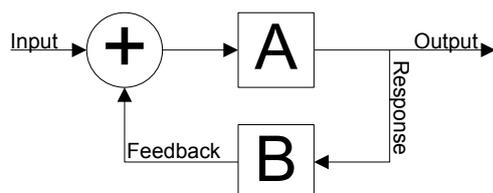

Atmospheric water vapour from evaporation stays on average 9.1 days in the atmosphere before it condenses and, finally, falls down as precipitation, thus forming the water balance (Eq. 3) (Baumgartner and Liebscher, 1996):

$$P = E - R - \Delta S \quad (\text{Eq. 3})$$

, where precipitation ( $P$ ) results in surface and subsurface runoff ( $R$ ), evaporation ( $E$ ), and  $\Delta S$ , describing the change in water storage, e.g., within the soil, the snowpack, ice or water bodies.

## 7.2. *Feedbacks in the Coupled System*

In any dynamic system, an external impulse (=energy input) (+) results in a response. The process-response system describes the connection between cause and effect as a function of time (Oke, 1987). A feedback occurs when the result of an initial process (A) triggers changes in a second process (B), that in turn influences the initial one (see Figure 1.2-1) (IPCC, 2001).

**Figure 7.2.1: Impulse-response and feedback mechanisms.**

Thereby, feedbacks may amplify (positive feedback) or dampen (negative feedback) the initial perturbation (Bridgman and Oliver, 2006). Consequently, a chain of mutually influencing effects starts, until a stable equilibrium is readjusted. While forcings are defined to be external to a system, feedbacks are describing internal processes.

The land-atmosphere system is characterized by strong positive and negative feedback loops that are yet little understood (Bridgman and Oliver, 2006; IPCC, 2007a). A simple example is the snow or ice-albedo positive feedback loop whereby snow or ice melting exposes more dark ground, which in turn leads to lower albedo. This results in lower short-wave reflection and increasing heat absorption that in turn causes higher air temperature and again more snow melt. A reduction in vegetation, e.g., due to urbanization, deforestation or a reduction in leaf area or in roots, results in reduced transpiration which yields in an increase of sensible heat at the costs of latent heat. Thus, less evaporative cooling is warming the near surface temperature, which in turn affects plant transpiration (Kabat et al., 2004). Low soil moisture may also result in less evaporative cooling, thereby affecting convection, precipitation and air temperature that in turn feed back to soil moisture (Seneviratne et al., 2010; Fischer et al., 2007a). Studies of the summer 2003 heat wave demonstrated the importance of soil moisture in terms of its impact on atmospheric processes (Schär et al., 2004; Loew et al., 2009; Fischer et al., 2007b).

### **7.3. Land Surface Heterogeneity**

The land surface fluxes are strongly related to the land surface characteristics. Thereby, the land surface is highly variable in all aspects in space, such that measurements taken one metre or two apart may report substantial differences in everything from soil moisture, through soil characteristics, to the type of vegetation (Pitman, 2003; Kabat et al., 2004). The enormous spatial variability of land cover, soil and the topography, due to their different properties is described in this thesis by the land surface heterogeneity. Thereby, the combination of the land cover, soil and topographic characteristics result in highly complex spatial differentiations and temporal dynamics of individual hydrological processes (Kabat et al., 2004), thus affecting the atmosphere.

The land cover, soils and the topography by slope, aspect and elevation control how much energy received from the sun is returned to the atmosphere (Monteith and Unsworth, 2008). Also, the terrain elevation is an important roughness property and also affects the air temperature with strong impacts, e.g., on mountainous snow cover. The soils have different hydraulic properties, such as texture and pore-size distribution. They determine, e.g., the infiltration rate, soil water tension and maximum soil water content.

Because of different thermodynamic properties, such as thermal conductivity and heat capacity, different radiation properties, such as albedo and emissivity, and different roughness properties, and different hydraulic properties, the land cover and land use strongly influences atmosphere processes. Thereby, vegetated land elementary differs from non-vegetated surfaces, such as open water, bare soil, snow and ice, rock or urban areas. Besides, a broad palette of different types of vegetation exists, such as deciduous broadleaf and coniferous forest or grassland. The behaviour of the stomata resistance and, with changing vegetation phenology, leaf area index (LAI), root depth and albedo are important vegetation properties for plant transpiration (Bach, 1995).

Anthropogenic impacts upon the land through intensive agriculture, deforestation and urbanization, tremendously changed the land surface, with large effects on climate (Bridgman and Oliver, 2006; Kabat et al., 2004; IPCC, 2007b).

The spatial heterogeneity of the land surface and the temporal variability at which land surface processes take place both are major challenges in modelling the land surface. With decreasing spatial scale and aggregation, the precision of the land use and land cover, the soil

and orography information is decreasing. The homogenization of these datasets in coarse scaled models leads to an information loss. The spatial distribution and spatial combination of soil, topography and vegetation type are essentially important in order to provide the prevailing conditions and properties at a certain point to the model. The parameterization of different soil types and land use/cover types describe the hydraulic, phenological, thermal and energetic properties. With increasing spatial scale, more individual plants can be located, resolved, parameterized and distinguished by the model. An increase of spatial resolution is increasing computational resources with square weight. Since computational resources are limited, a coarse resolution is often chosen to shorten the simulation time, e.g., for long-term scenario simulations in climate models.

#### **7.4. State of the Art in RCMs**

A climate model is the numerical representation of the climate system based on the physical, chemical and biological properties of its components, their interactions and feedback processes, and accounting for all or some of its known properties (IPCC, 2001). Regional climate models (RCMs) being forced with exogenous model data on the lateral boundaries of the limited modelling area, extend the coarse description of atmospheric processes within GCMs towards increased spatial resolution, thereby capturing the regional structures of each model grid point on continental scales (Giorgi, 2001; Jacob et al., 2007; Kueppers et al., 2008; Laprise, 2008; Mc Gregor, 1997; Michalakes, 1997; Quintanar et al., 2009; Schär et al., 2004; Stocker, 2004; Zampieri et al., 2011). At present, RCMs' grid squares are usually around  $50 \times 50 \text{ km}^2$ . RCMs have always taken into account the interrelationships between the land surface and the atmosphere (Pitman, 2003). Therefore, the land surface energy and matter fluxes, representing the lower boundary conditions, are passed to the atmospheric part of the RCM.

Land surface models (LSMs) within RCMs have undergone large improvements in the past decades (van den Hurk et al., 2011). The Project for the Intercomparison of Land-Surface Parameterization Schemes (PILPS) started 1992 for evaluating and intercomparing LSMs within a common framework, with the aim of improving the understanding of current and future parameterization schemes used to represent regional to continental scales (Dickinson, 1995; Famiglietti and Wood, 1991; Polcher et al., 1998; Wood et al., 1998; Yang et al., 1998; Henderson-Sellers et al., 1996; Timbal and Henderson-Sellers, 1998; Pitman and Henderson-Sellers, 1998). One of the key findings within PILPS was the need to run LSMs decoupled from the host atmospheric model for model comparison and comparison with measurements, and the recognition of the need to formally conserve energy and matter (van den Hurk et al., 2011). The complexity, spatial heterogeneity and temporal variability of land surface processes and the need for a more detailed view of it is a long standing discussion in atmospheric sciences (Henderson-Sellers et al., 1995; Henderson-Sellers et al., 2008; Dickinson, 1995; Dickinson et al., 1991). There is evidence that more advanced and robust LSMs, which increasingly consider the spatial heterogeneity and complexity of land surface biophysical and hydrological processes in the soil-plant-atmosphere continuum on a finer scale will reduce the uncertainties in the current modelling of land-atmosphere processes (Essery et al., 2003; Hagemann et al., 2001; Koster et al., 2004; Laprise, 2008; Molod and Salmun, 2002; Seth et al., 1994; Yu, 2000).

Therefore, huge efforts are currently being made in several projects to resolve the spectrum of land surface challenges within the International Geosphere-Biosphere Programme (IGBP) and the World Climate Research Programme (WCRP), such as the Integrated Land Ecosystem-Atmosphere Processes Study (iLEAPS), the Global Energy and Water Cycle Experiment (GEWEX), and the Global Land Atmosphere System Study (GLASS) framework which was launched in 1999 (van den Hurk et al., 2011). The main focus of attention of GLASS is model development and evaluation, thereby enclosing various projects, such as the Global Soil Wetness Project (GSWP) (Dirmeyer, 2011), the Global Land Atmosphere Coupling Experiment (GLACE) (Koster et al., 2004; Koster et al., 2006), the Local coupled land-atmosphere Modelling Project (LoCo) (van den Hurk and Blyth, 2008) and the Land-Use and Climate, Identification of robust impacts (LUCID) project (Pitman et al., 2009). These projects aim at transforming the ability of LSMs to realistically represent land surface processes and fluxes and the complex interactions and feedbacks with the atmosphere to capture the climate sensitivity at different spatial scales. Further, they work on improving the specification of the land surface characteristics of their temporal and spatial variability, e.g., to assess the sensitivity of surface fluxes to the specification of canopy conductance, leaf area index, surface roughness and rooting depth.

Due to the latest progress, LSMs have developed from simple bucket schemes to more realistic land surface representations, including more and more aspects of physical land surface modelling, anthropogenic effects and interactions (Pitman, 2003). Vegetation dynamics and their responses to environmental conditions, surface and subsurface hydrology, dynamic evolution of snowpack and the representations of urban, lake and biogeochemical processes are recently implemented in LSMs (Pitman, 2003; van den Hurk et al., 2011).

However, the major concern of current LSMs is the sufficient representation of land heterogeneity at the local to regional scale and sub-grid-scale processes (Bridgman and Oliver, 2006; IPCC, 2007b; Pitman, 2003). By not allowing for small-spatial-scale processes, their capacity to model future climate change is limited, especially with respect to hydrological consequences and their role of coupling and feedbacks (Bridgman and Oliver, 2006; IPCC, 2007b; Pitman, 2003). Current key uncertainties in RCMs include the role of the soil, the cryosphere, human-induced impacts on the land use, land-atmosphere interactions as well as land surface parameters, such as vegetation parameters or the depth of the hydrological soil reservoir (IPCC, 2007a). Thereby, they typically ignore horizontal movement of surface and sub-surface water within the soil. They do not capture basic

hydrological processes, such as permafrost, the impact of frozen soil on infiltration or soil heat transfer, roots and their effects on moisture availability, the whole issue of groundwater (IPCC, 2007b; Muerth and Mauser, 2012; Pitman, 2003). Yet, most of the LSMs do not incorporate site-specific soil properties or the influence of soil moisture on heat transfer (Muerth and Mauser, 2012).

## **7.5. State of the Art in LSHMs**

Hydrologists have developed empirical, conceptual and more and more physically-based land surface hydrological models (LSHMs) spanning a wide range of complexity.

They have developed from simple reservoir models, producing the runoff unit hydrograph as a response to precipitation input for basins and sub-basins, to not-calibrated and physically based models, taking in detailed into account the spatial properties of the catchment (Mauser and Bach, 2009).

They go beyond reproducing runoff at gauges of small scale catchment areas and now consider in detail the hydrologic land surface processes, thereby capturing land surface heterogeneity with high spatial resolution of about  $1 \times 1 \text{ km}^2$  and are more and more extending to continental scales (Bharati et al., 2008; Devonec and Barros, 2002; Garcia-Quijano and Barros, 2005; Kuchment et al., 2006; Kunstmann et al., 2008; Ludwig and Mauser, 2000; Mauser and Bach, 2009; Schulla and Jasper, 1999; Wagner et al., 2009). Thereby, they describe the characteristics of a wide range of natural vegetation and agricultural crops. The physically based models aim at understanding the interactions between the different land surface and subsurface compartments, namely soil, vegetation, snow and ice, groundwater in producing the resulting river runoff (Ludwig and Mauser, 2000; Ludwig et al., 2003a; Ludwig et al., 2003b; Mauser and Schädlich, 1998; Mauser and Bach, 2009; Strasser, 1998). They include detailed descriptions of vertical and lateral soil water, ground water, including related flow regulations and man-made structures (Koch et al., 2011). They describe in detail mass and heat transfer within the soil (Muerth and Mauser, 2012), incorporating the effects of frozen soils, vegetation dynamics (Hank, 2008), snow and ice dynamics (Prasch et al., 2006; Prasch et al., 2011; Strasser et al., 2007; Weber et al., 2010) as well as mass and heat exchange with the atmosphere. Thereby, they capture the major land surface processes in the soil-plant-atmosphere continuum with high spatial and temporal resolution (Loew, 2008; Loew et al., 2009; Marke, 2008; Strasser and Mauser, 2001).

The meteorological drivers as input to LSHMs can either be provided by measurements or by RCMs. The latter has been used for recent hydrological impact studies on climate change scenarios (Marke, 2008; Marke et al., 2011; Kotlarski et al., 2005; Kunstmann and Stadler, 2005). A major issue in these studies is the scale gap between the RCMs and the hydrological impact models, since hydrological models usually act on much finer spatial scale in order to

resolve the relevant hydrological processes realistically (IPCC, 2007b; Marke, 2008). Thereby, the meaning of large spatial domains is increasing for hydrological models with respect to capture impacts of hydrological dynamics and processes on climate and climate change (Cloke and Hannah, 2011).

In contrast to LSMs designed for atmosphere applications, the atmosphere is usually considered as an exogenous driver only. Therefore, they do not allow for interactions and feedbacks between the atmosphere and the land surface.

## **7.6. Research Objectives – Bi-directional Coupling Approach**

While RCMs allow for exchanging fluxes in a coupled land-atmosphere system, their representation of the land surface is usually coarse. Often, they do not sufficiently capture important land surface hydrological processes or even neglect hydrologically important land surface characteristics. On the other hand, LSHMs describe the processes at the land surface, including the surface energy, radiation and water balance with high spatial and temporal detail. However, they do not allow for feedbacks between the land surface and the atmosphere, since they usually consider the atmosphere as an exogenous driver only. Nevertheless, both models use physically based parameterizations and formulations for describing the same land surface processes, thereby closing the energy balance at the land surface and following the rules of mass and energy conservation.

Therefore, the basic idea of this thesis was the combination of the advantages of current LSHMs with the advantages of existing RCMs. The recent developments in LSMs show that there is a huge scientific demand for improving LSMs within RCMs. In the hydrological community one is used to deal with climate data, though, the impact of hydrological changes on climate has never been discussed as explosive as today. Nevertheless, the scientific tools for detailed hydrological simulations are not able to cope with hydrological impacts on climate and resulting feedbacks.

Therefore, a bi-directional coupling approach was developed, that allows for a coupling between a LSHM with the atmospheric part of a RCM across the different scales between both models. Coupling a LSHM with a RCM has never been investigated explicitly. The potential of such an approach has already been recognized e.g. in Chen and Dudhia (2001), who suggests to apply LSHMs originally designed for surface hydrology to atmospheric applications. Van den Hurk et al. (2011) stimulates a rethinking of the concept of fixed land models that are driven by fixed atmosphere forcings in various scientific arenas (weather prediction, catchment hydrology, ocean science).

By coupling a LSHM bi-directionally with a RCM, the RCM would benefit from the advanced understanding and representation of the land surface from the LSHM. In return, the LSHM would profit from the possibility to include feedback effects between the high resolution land surface and the atmosphere.

Overall, these improvements could lead to a scientific benefit in modelling and understanding land-atmosphere interactions and, thus, reduce uncertainties within current climate projections.

While LSHMs already deal with studying of the land surface under the influence of changing meteorological conditions, the bi-directional coupling approach opens the opportunity for hydrological models to investigate hydrological impacts at the land surface on the climate, e.g., due to climate or land use change. This includes possible benefits, impacts and links to related issues, such as water and food supply, energy, health, and biodiversity.

Within the framework of the GLOWA-Danube project within which this work took place, the developed coupling approach was implemented in the LSHM PROMET and the RCM MM5. These models were applied and adapted for the modelling domain of Central Europe.

## 8. PUBLICATIONS

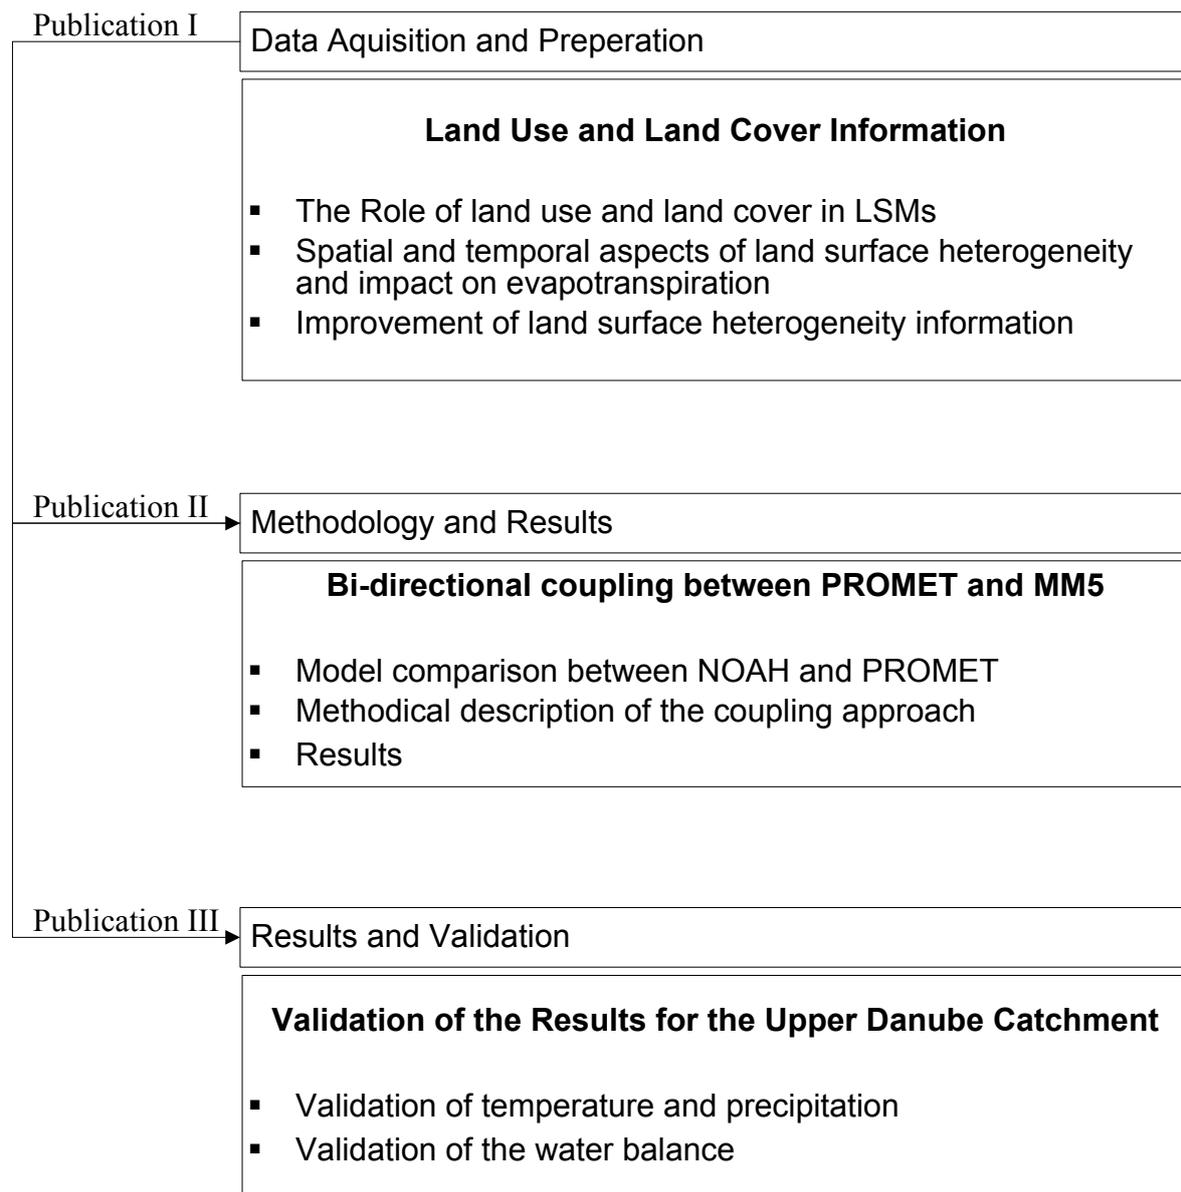

### 8.1. *Framework of the Thesis*

This cumulative thesis includes three integral publications forming the framework of this thesis. Thereby, each publication can be put in the overall context of the thesis, addressing the research objectives and goals as described. Hence, Figure 8.1.1 illustrates the continuity of the publications within the framework.

While the first publication describes an integral method for improving land use/cover heterogeneity information, it can be regarded as a substantial part of the data acquisition and preparation for the bi-directional coupling approach between PROMET and the atmospheric part of MM5 that is further described in publication II.

The main focus of publication II is the model comparison between the LSM within the RCM MM5 (NOAH) and the LSHM PROMET and the methodical description of the coupling approach. On the basis of the model comparison, the differences between the model results are explained.

While results are shown and discussed within publication II for the whole coupling domain of Central Europe, they are finally validated and compared with measurements for the specific Upper Danube watershed in the study of publication III.

**Figure 8.1.1: Continuity of the publications in the framework of the thesis.**

## **8.2. Overview of the publications**

The dissertation encloses the following three integral publications:

### **Publication I**

Zabel, F., Hank, T.B., Mauser, W.: Improving arable land heterogeneity information in available land cover products for land surface modelling using MERIS NDVI data. *Hydrol. Earth Syst. Sci.*, 14, 2073–2084, Doi:10.5194/hess-14-2073-2010, 2010

### **Publication II**

Zabel, F., Mauser, W., Marke, T., Pfeiffer, A., Zängl, G., and Wastl, C.: Inter-comparison of two land-surface models applied at different scales and their feedbacks while coupled with a regional climate model, *Hydrol. Earth Syst. Sci.*, 16, 1017-1031, Doi:10.5194/hess-16-1017-2012, 2012.

### **Publication III**

Zabel, F. Mauser, W.: Analysis of feedback effects and atmosphere responses when 2-way coupling a hydrological land surface model with a regional climate model. A case study for the Upper-Danube catchment, *Hydrol. Earth Syst. Sci. Discuss.*, 9, 7543-7570, Doi: 10.5194/hessd-9-7543-2012, 2012.

### **8.3.     *Transition to Publication I***

In the framework of this thesis, the first paper is about the acquisition and preparation of land surface information (see Figure 8.1.1). The aim of this paper is to develop a yet not existing high resolution land use/cover dataset for the later use with PROMET in the bi-directional coupling approach for Central Europe, covering the large spatial area of  $1170 \times 1170 \text{ km}^2$ . The large spatial extend was necessary to allow for feedbacks within the bi-directional coupling approach with the RCM, since climate models are designed to simulate large spatial scales.

The study forms an integral part of this thesis, since the compiled land surface information is essential for the further coupling approach. The land cover information has strong impact on both albedo and partitioning of energy and matter fluxes from the surface to the atmosphere (Ge et al., 2007). It determines the type of vegetation and thereby the seasonal development of plant phenology, canopy structure and leaf area, which in turn, through vegetation height and leaf area index, determines the aerodynamic and evapotranspirative properties of the land surface.

Therefore, this publication describes a developed approach, combing existent land use classifications with high resolution remote sensing NDVI data and statistical datasets. Thus, it is shown that land surface heterogeneity, including the crop variability within arable land, is an essential aspect for hydrological modelling with high impact on energy and matter fluxes. The impact of land surface heterogeneity information on the simulation of evapotranspiration is exemplarily demonstrated for the Upper Danube basin.

#### **8.4. *Publication I***

Zabel, F., Hank, T.B., Mauser, W.: Improving arable land heterogeneity information in available land cover products for land surface modelling using MERIS NDVI data. *Hydrol. Earth Syst. Sci.*, 14, 2073–2084, Doi:10.5194/hess-14-2073-2010, 2010

# Improving arable land heterogeneity information in available land cover products for land surface modelling using MERIS NDVI data

**F. Zabel<sup>1</sup>, T. B. Hank<sup>1</sup> and W. Mauser<sup>1</sup>**

## **Abstract**

Regionalization of physical land surface models requires the supply of detailed land cover information. Numerous global and regional land cover maps already exist but generally, they do not resolve arable land into different crop types. However, arable land comprises a huge variety of different crops with characteristic phenological behaviour, demonstrated in this paper with Leaf Area Index (LAI) measurements exemplarily for maize and winter wheat. This affects the mass and energy fluxes on the land surface and thus its hydrology. The objective of this study is the generation of a land cover map for central Europe based on CORINE Land Cover (CLC) 2000, merged with CORINE Switzerland, but distinguishing different crop types. Accordingly, an approach was developed, subdividing the land cover class arable land into the regionally most relevant subclasses for central Europe using multiseasonal MERIS Normalized Difference Vegetation Index (NDVI) data. The satellite data were used for the separation of spring and summer crops due to their different phenological behaviour. Subsequently, the generated phenological classes were subdivided following statistical data from EUROSTAT. This database was analysed concerning the acreage of different crop types. The impact of the improved land use/cover map on evapotranspiration was modelled exemplarily for the Upper Danube catchment with the hydrological model PROMET. Simulations based on the newly developed land cover approach showed a more detailed evapotranspiration pattern compared to model results using the traditional CLC map, which is ignorant of most arable subdivisions. Due to the improved

temporal behaviour and spatial allocation of evapotranspiration processes in the new land cover approach, the simulated water balance more closely matches the measured gauge.

## **Introduction**

The land surface and its properties are highly influenced by human activities such as agriculture or surface sealing. Land use/cover information is a key component of climate and hydrological models since the land cover primarily controls the energy fluxes on the land surface (Monteith and Unsworth, 1990; Lu and Shuttleworth, 2002; Masson et al., 2002). In a land use/cover map, each pixel of the land surface is associated to a label that characterizes the land use/cover following a predefined nomenclature. The accuracy of land use/cover products has a strong effect on the model results (Ge et al., 2007). The regional hydrological relevance of the mapped agricultural land cover heterogeneity is the focus of this paper.

### **Existing land use/cover maps**

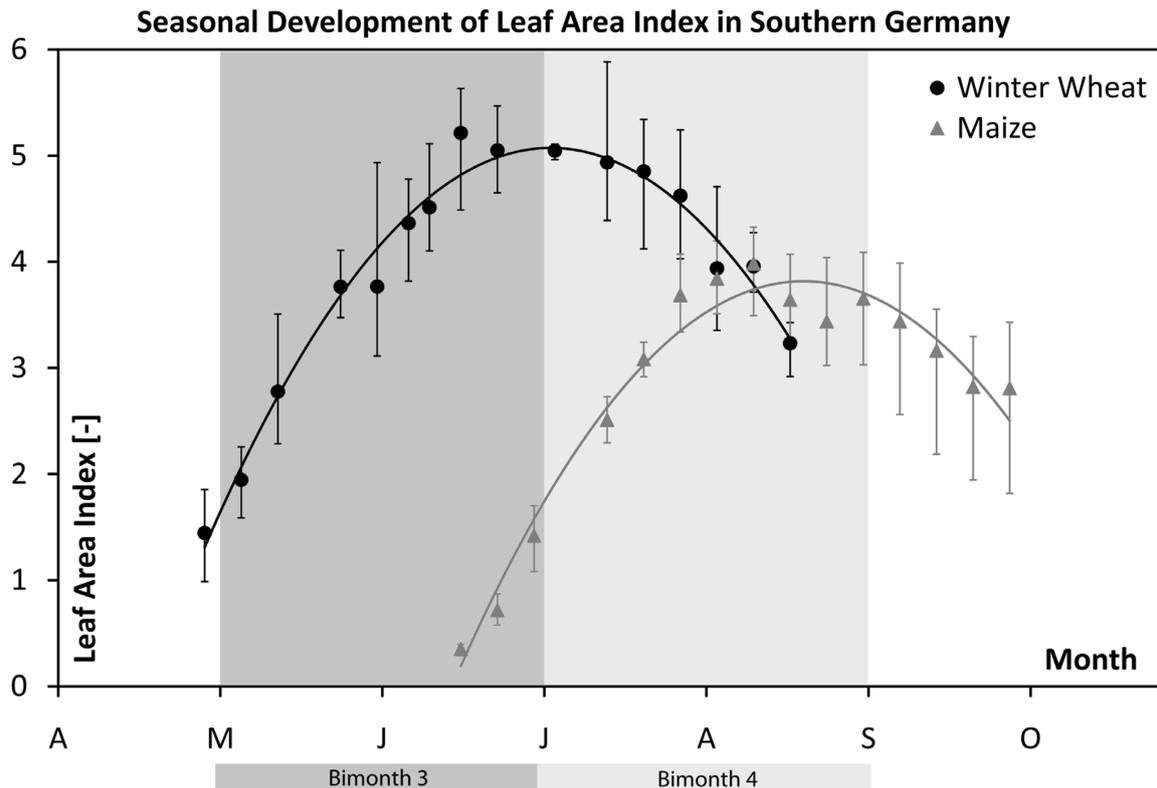

Thanks to the development of new remote sensing sensors with improved spatial and spectral resolution, various global, regional and local classifications with a spatial resolution of 1 km or even higher exist (Defries and Belward, 2000; Cihlar, 2000; Herold et al., 2007). ECOCLIMAP, for example, is a well-known global land cover product with a spatial resolution of 1 km (Masson et al. 2002). The Global Land Cover (GLC) 2000 classification compiled by the Joint Research Centre (JRC) and the European Space Agency (ESA) using SPOT-4 remote sensing data also features a spatial resolution of 1 km (Bartholomé and Belward, 2005). As a successor of GLC 2000, GLOBCOVER uses ENVISAT MERIS fine resolution data (300 m) for mapping the global land cover (Arino et al., 2007; Defourny et al., 2006). The MERIS images used for the GLOBCOVER product were acquired between January 2005 and June 2006 within the frame of the ESA GLOBCOVER project (Bicheron et al., 2008). The data are provided by POSTEL (Pôle d'Observation des Surfaces continentales par TELédétection). These land cover products use different thematic legends but are fully compatible with the LCCS (Land Cover Classification System) used by the Food and Agriculture Organisation (FAO) and the United Nations Environment Programme (UNEP), which comprises 22 different types of land cover (Di Gregorio et al., 2000). As these maps provide global land cover information, they may not necessarily be suitable for regional or local studies. The CORINE Land Cover (CLC) classification is the most detailed regional land cover product available for Europe. It distinguishes 44 classes of land cover with a

spatial resolution of 100 m (Heymann et al., 1994; EEA, 2006; Bossard et al., 2000). The data are available for download at the EEA (European Environmental Agency). Many studies comparing the available land cover products e.g. CLC 2000 and GLC 2000 (Neumann et al., 2007; Herold et al., 2007) provide information on applicability and accuracy of the different maps.

### **Heterogeneity of arable land**

Energy and matter fluxes are influenced directly by the land surface. Vegetation is a key element for SVAT (Soil-Vegetation-Atmosphere-Transfer) models, regarding its function as an interface between the land surface and the atmosphere (e.g. as a regulator of transpiration) (Monteith and Unsworth, 1990). The land surface has a strong feedback effect on the atmosphere and hence on the climate (Bounoua et al., 2000). Unfortunately most global and regional land cover datasets derived from satellites group croplands into just a few categories, thereby excluding information that is critical for answering key questions of current research (Monfreda et al. 2008; Herold et al., 2007). According to CLC, arable land accounts for 46 % of the study area and thereby represents the class with the largest proportion of all land cover classes in central Europe. However, croplands include a variety of species with different phenology and physiology (Lokupitiya et al., 2009).

Exemplarily shown in Figure 8.4.1 for maize and winter wheat based on the temporal development of Leaf Area Index (LAI), the growth cycles of specific crops may differ largely. While the main growth period of winter wheat occurs between May and June, the measurements show that maize grows fastest between July and August.

**Figure 8.4.1: Seasonal development of LAI for maize and winter wheat for a test side in southern Germany (April to October 2004). Vertical error bars represent the minimum and maximum observations.**

The ground based LAI measurements shown in Figure 8.4.1 were collected during a field campaign conducted in southern Germany (approx. 25 km south-west of the city of Munich), monitoring maize and winter wheat stands during the growing season in 2004. The data points represent values of total LAI, measured by means of the Plant Canopy Analyzer LAI-2000 instrument (LICOR Inc., Lincoln, NE, USA). Each point corresponds to the average of five individual sample points within a winter wheat and a maize stand respectively. Vertical error bars indicate the observed minimum and maximum within each of the test fields. Although the investigated stands were comparably homogenous and strongly developed, which may cause the absolute values to appear slightly elevated compared to less well developed fields, the general seasonal growth pattern can be considered representative for these crops in southern Germany. The distinct difference of the temporal dynamics of leaf area accumulation and decrease of wheat and maize accounts well for the characteristic seasonal growth patterns of both crops. While the wheat site was ripening during July and already harvested at the beginning of August, the maize site did not reach its maximum development before the beginning of September. Since the displayed values were derived from non-destructive measurements, only the total LAI of the crops can be considered. If the effect of chlorophyll decomposition during the ripening phase is additionally taken into account, the seasonal

disparities between both crops would become even more apparent. Nonetheless, the readings displayed in Figure 1 clearly indicate that there is a temporal gap in the seasonal behaviour of maize and winter wheat of about 2 months. Bsaibes et al. (2009) showed similar results for temporal dynamics of LAI in southern France with a temporal shift forward in time of approximately 2 weeks. Those findings support the assumption of this typical seasonal behaviour of LAI development for the entire European area of interest.

The different phenology not only has an impact on the primary productivity during the growing season but also on the energy and matter fluxes such as evapotranspiration, sensible heat flux or long- and shortwave outgoing radiation as well as on CO<sub>2</sub> fluxes or soil moisture (Lokupitiya et al., 2009). This must be taken into account when modelling the processes on the land surface. A diverse vegetation phenology within the arable land makes it necessary to split this class into subdivisions of different crop types. Approaches for unmixing cropland out of multitemporal remote sensing data have been carried out successfully using NOAA/AVHRR time series (Probeck et al., 2003). Studies for higher resolution information nevertheless show that amounts of manual interpretation and cloud-free high spatial resolution imagery are required for operational implementation over large areas and in multiple years (Lobell and Asner, 2004). However, the approach described in this paper uses existing land cover products improving them with the help of remote sensing products combined with statistical data.

## **Method**

### **Area of interest**

The study area is situated in Central Europe and extends 1170 km north-south by 1170 km east-west including 18 European countries, 6 of them not being members of the European Union (Figure 8.4.2). Plains like the Po Valley, uplands like in central Germany and the Alps that mark a climatic boundary between the temperate latitudes and the Mediterranean climate dominate the landscape. Altitudes are ranging from the Mont Blanc in the French Alps (4.810 m) to the Atlantic Ocean in the north-west and the Mediterranean Sea in the south. In between, a wide range of different land covers occurs, which are strongly influenced by man. The area is characterized by intense agriculture especially within the fertile lowlands like the Upper Rhine or the Po Valley.

**Figure 8.4.2: Topography (based on SRTM data) of the area of interest, showing the European countries as well as the boundaries of the Upper Danube catchment.**

### Hydrological model

The physically based hydrological model PROMET (Processes of Radiation, Mass and Energy Transfer) used in this study to investigate the regional impact of agricultural land information was developed and validated for the Upper Danube catchment (Mauser and Bach, 2009; Mauser and Schädlich, 1998). The model can be operated on variable scales, but was applied with a spatial resolution of 1 km in this study. Hence, a land use/cover scheme that

serves as an input for PROMET at least needs the same spatial resolution. As PROMET uses its own land use/cover parameterization, the nomenclature of the land use/cover classification and the model parameterization have to match. The parameterization scheme in PROMET discerns 27 classes (Table 8.4.1) within the first 17 are different types of land occupied by agriculture. The parameterization was created for the watershed of the Upper Danube. The included classes therefore are restricted to the regional particularities of the land cover for this region (Ludwig et al., 2003). The parameterization of individual land surface classes is due to physical plant properties gathered from measurements. Therefore, the plant parameterization in PROMET is restricted to specific plant types. Accordingly, mixed vegetation classes like "mixed forest" are avoided in PROMET. The motivation for developing a regional land cover map for the larger extent of the area of interest is the need for a detailed description of the European land cover that allows for two-way coupling of PROMET with the regional climate model MM5 (Zabel et al., 2010).

**Table 8.4.1: PROMET land use/cover classes.**

<b>ID</b>	<b>PROMET class</b>	<b>ID</b>	<b>PROMET class</b>	<b>ID</b>	<b>PROMET class</b>
1	Extensive Grassland	10	Potato	19	Residential Built-Up

9	Oleaginous	18	Industrial Built-Up	27	Water

## Land use/cover classification

### ***Fusion of CLC 2000 and CLC Switzerland and adaptation to PROMET***

As this study is concentrating on central Europe, the CLC 2000 (version 9/2007) classification was well suited for further processing in order to allow for a later use with the PROMET model. CLC 2009 is in progress but not available for all European countries, yet. Since the 44 CLC 2000 classes do not match the parameterization of vegetation and land cover in PROMET, a transformation from the CLC 2000 classification system to the thematic legend

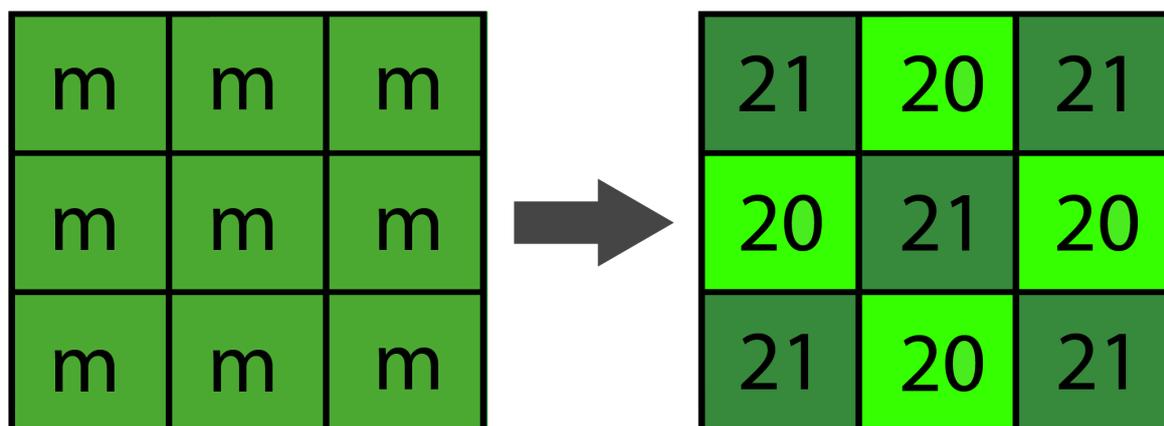

of PROMET was necessary. This was done following the conversion scheme shown in Table 8.4.2.

**Table 8.4.2: Transformation of CORINE Land Cover 2000 into the PROMET classes.**

ID	LABEL3	ID	LABEL
1.1.1.	Continuous urban fabric	→ 19	Residential Built-Up
1.1.2.	Discontinuous urban fabric	→ 19	Residential Built-Up
1.2.1.	Industrial or commercial units	→ 18	Industrial Built-Up
1.2.2.	Road and rail networks and associated land	→ 18	Industrial Built-Up

2.4.1.	Annual crops associated with permanent crops	→	Arable Land
2.4.2.	Complex cultivation patterns	→	Arable Land
2.4.3.	Land principally occupied by agriculture, with significant areas of natural vegetation	→	Arable Land
2.4.4.	Agro-forestry areas	→ 21	Coniferous Forest
3.1.1.	Broad-leaved forest	→ 20	Deciduous Forest
3.1.2.	Coniferous forest	→ 21	Coniferous Forest
3.1.3.	Mixed forest	→ 20/21	50 % Deciduous Forest, 50 % Coniferous Forest
3.2.1.	Natural grasslands	→ 25	Natural Grassland
3.2.2.	Moors and heathland	→ 23	Wetland
3.2.3.	Sclerophyllous vegetation	→ 25	Natural Grassland
3.2.4.	Transitional woodland-shrub	→ 20	Deciduous Forest
3.3.1.	Beaches, dunes, sands	→ 22	Rock
3.3.2.	Bare rocks	→ 22	Rock
3.3.3.	Sparsely vegetated areas	→ 25	Natural Grassland
3.3.4.	Burnt areas	→ 25	Natural Grassland
3.3.5.	Glaciers and perpetual snow	→ 26	Glacier
4.1.1.	Inland marshes	→ 23	Wetland
4.1.2.	Peat bogs	→ 23	Wetland
4.2.1.	Salt marshes	→ 23	Wetland
4.2.2.	Salines	→ 23	Wetland
4.2.3.	Intertidal flats	→ 23	Wetland
5.1.1.	Water courses	→ 27	Water
5.1.2.	Water bodies	→ 27	Water
5.2.1.	Coastal lagoons	→ 27	Water
5.2.2.	Estuaries	→ 27	Water
5.2.3.	Sea and ocean	→ 27	Water

Although the CLC 2000 classes 'rice fields', 'vineyards', 'fruit trees & berry plantations', and 'olive groves' are not implemented in the parameterization of PROMET yet (as they are irrelevant in the Upper Danube catchment), they were not reclassified in order to be able to

introduce the crop specific parameterization to PROMET at a later point in time. The compiled classes 'arable land' and 'pasture', which are both not parameterized in PROMET, state the basis for a further processing. Since 'mixed forest' does not exist within the land cover nomenclature of PROMET, it was evenly distributed into the coniferous and deciduous forest category using a uniform pattern (Figure 8.4.3).

**Figure 8.4.3: Reclassification of forested areas labelled as 'mixed forest' (m) to an evenly distribution of deciduous (20) and coniferous (21) forest. The Pixels are alternately classified to coniferous and deciduous.**

Since Switzerland is missing within the CLC 2000, the map was completed with the CLC 1990 Switzerland classification having a spatial resolution of 250 m and again using a different nomenclature of land use/cover classification. Land use/cover change from 1990 to 2000 in Switzerland is supposed to be negligible. The transformation of the Swiss land cover classification to the PROMET classes is shown in Table 8.4.3.

**Table 8.4.3: Transformation of the CORINE Land Cover 1990 Switzerland into the PROMET classes.**

ID	LABEL1		ID	PROMET-LABEL
11	Urban fabric	→	19	Residential Built-Up
12	Industrial, commercial and transport units	→	18	Industrial Built-Up
13	Mine, dump and construction sites	→	18	Industrial Built-Up
14	Artificial non-agricultural vegetated areas	→	19	Residential Built-Up
21	Arable land	→		Arable Land
22	Permanent crops	→		Arable Land
23	Pasture	→		Pasture
24	Heterogeneous agricultural areas	→		Arable Land

33	Open spaces with little or no vegetation	→	25	Natural Grassland
41	Inland wetlands	→	23	Wetland
51	Inland waters	→	27	Water

As Table 8.4.3 demonstrates, CLC 1990 Switzerland has a lack of glaciers and no differentiation between coniferous and deciduous forest. The glaciers for Switzerland were added using the GLOBCOVER glacier classification (Bicheron et al. 2008) as a glacier mask for the new classification approach. Furthermore, the Swiss forest was divided into coniferous and deciduous forest by using statistical data of the Swiss Federal Statistical Office for each canton (Table 8.4.4).

**Table 8.4.4: Statistical distribution of coniferous and deciduous forest [km<sup>2</sup>] for each Swiss canton (Swiss Federal Statistical Office, 2004).**

Canton	Coniferous Forest	Mixed Coniferous Forest	Mixed Deciduous Forest	Deciduous Forest	Total Forest	Not classified
Région Lémanique	955	414	278	226	1873	37
Espace Mittelland	1105	856	693	417	3070	80
Nordwestschweiz	108	167	229	149	654	
Zürich	165	143	136	46	489	
Ostschweiz	1708	494	361	231	2794	65
Zentralschweiz	564	327	208	95	1195	19
Tessin	351	189	139	601	1279	26

First, all Swiss forested area located at elevations above 1200 meters was generally reclassified to coniferous forest according to the following rule.

If the land cover was 'forest' and the altitude was higher than 1200 m, then the land cover was reclassified to 'coniferous forest'.

This corresponds to the climatic limit of deciduous forest in Switzerland. The underlying digital elevation model (DEM) used for this decision consisted of 90 m Shuttle Radar Topography Mission (SRTM) data. After the entire forest above 1200 m was identified as coniferous forest, the rest of the forested area was reclassified following the statistical allocation for each canton (Swiss Federal Statistical Office, 2004) (Table 8.4.4), subtracting the coniferous forested area above 1200 m that has already been classified. The sections 'mixed coniferous forest' and 'mixed deciduous forest' of the statistics each have a fraction of 50 - 90 % of coniferous or deciduous forest respectively but were regarded as unmitigated (100 %) coniferous or deciduous forest.

After the modified and reclassified CLC 2000 and CLC 1990 Switzerland were merged to one map, more adaptations were necessary for a subsequent division of the class 'natural

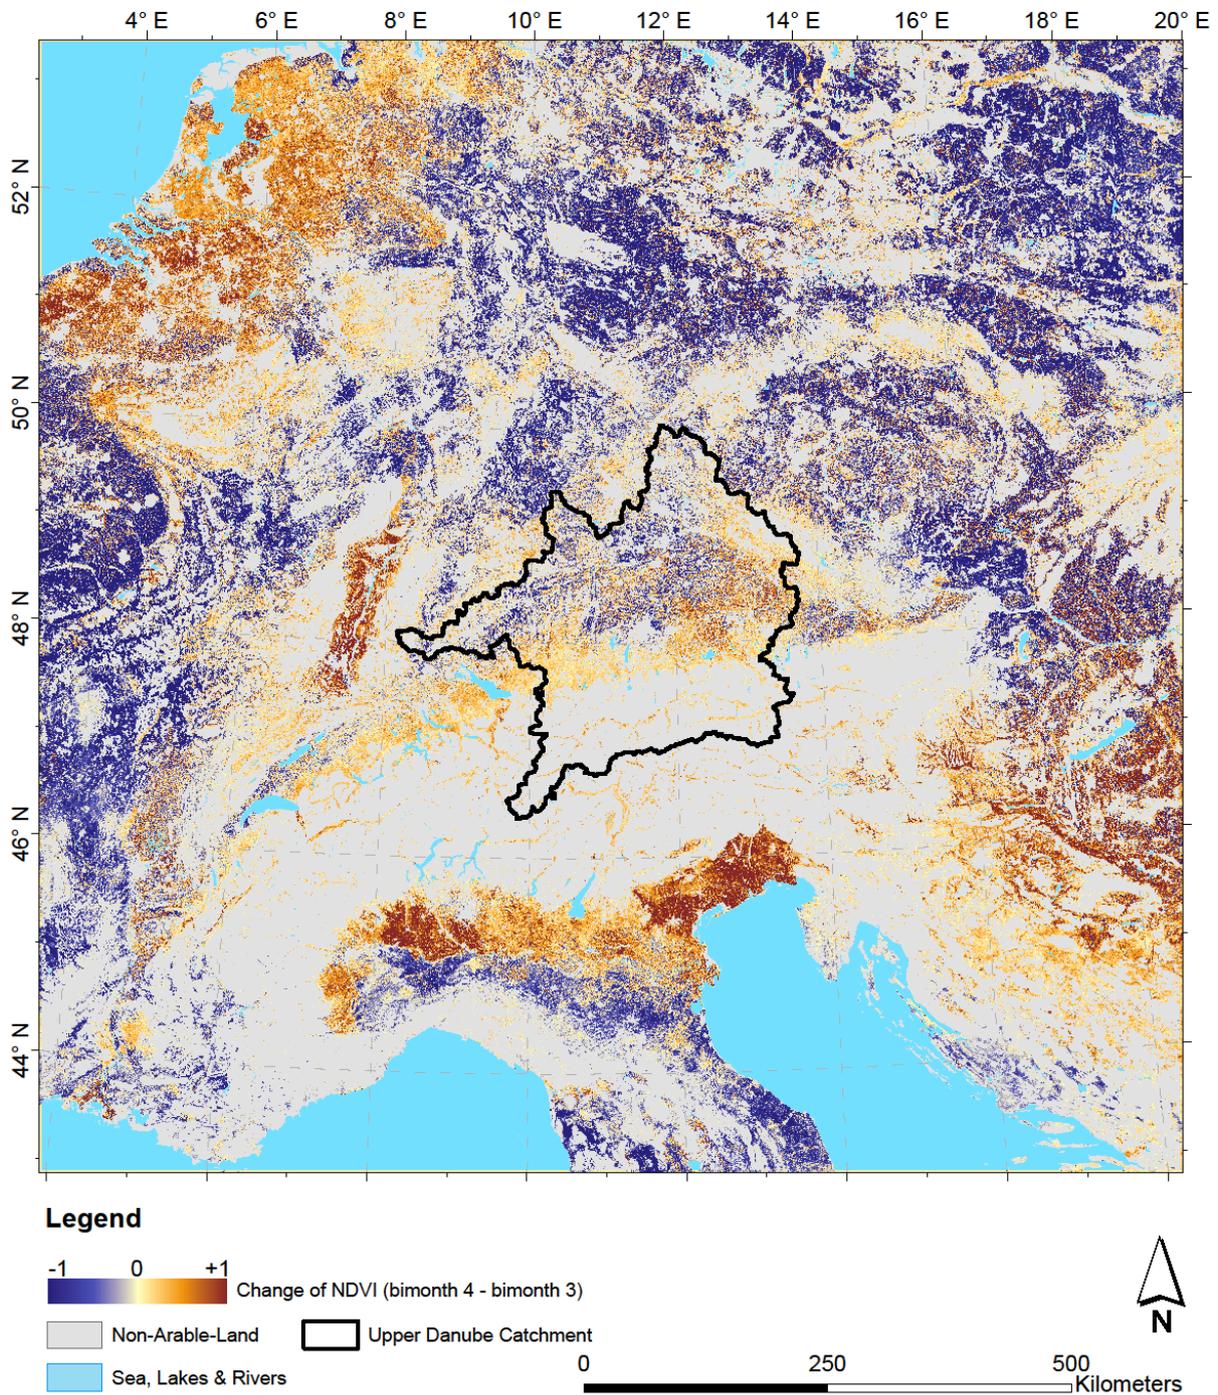

grassland'. In order to meet the regional characteristics of the alpine vegetation, the class 'natural grassland' was further reclassified to 'rock' or 'alpine vegetation' based on three assumptions:

- If the land cover was 'natural grassland' and the altitude was higher than 2400 m, then the land cover was reclassified to 'rock'.
- If the land cover was 'natural grassland' and the altitude was between 1400 m and 2400 m, then the land cover was reclassified to 'alpine vegetation'.
- If the land cover was 'natural grassland' and the slope was higher than 30 %, then the land cover was reclassified to 'rock'.

### ***Subdivision of arable land via MERIS NDVI data***

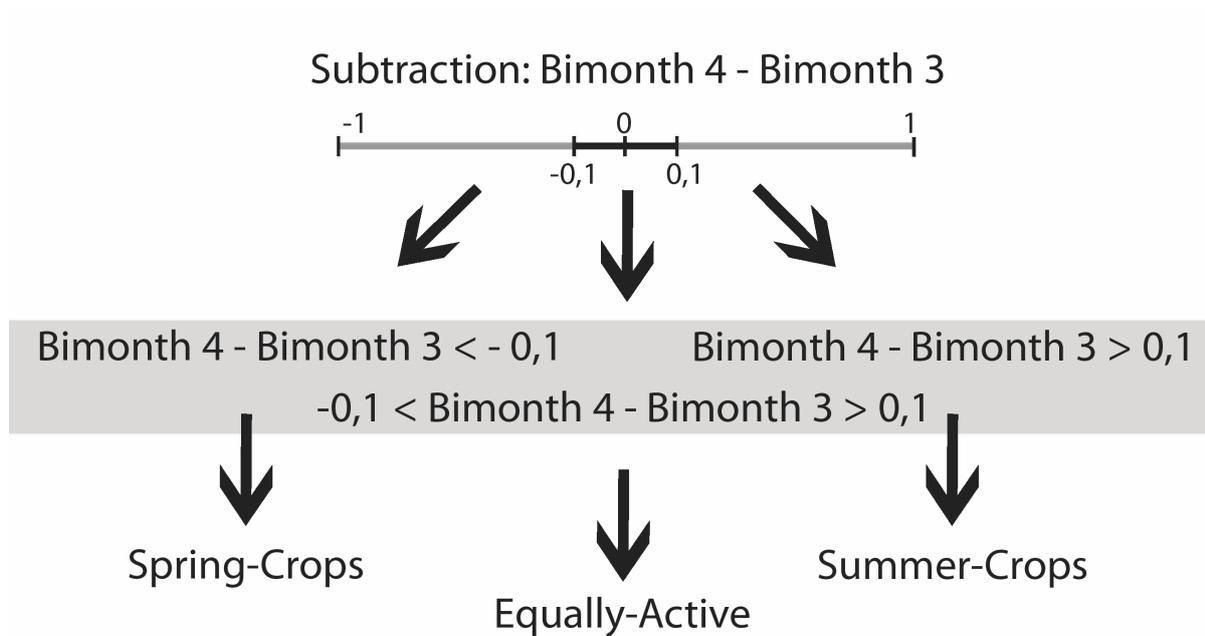

Thus, a land cover map for central Europe was created by merging the CLC 2000 and CLC Switzerland into one consistent land use/cover map and translating them into the PROMET nomenclature. Further, it was necessary to divide the class 'arable land' into subclasses in order to cover the natural heterogeneity of different crop types in central Europe. Figure 8.4.1 demonstrates the different phenological development of maize and winter wheat, using LAI as example. The context of these measurements can be transferred to the Normalized Differenced Vegetation Index (NDVI), because of a strong correlation between LAI and NDVI (Baret and Guyot, 1991; Bach, 1995). In order to classify the distinct phenological behaviours of different crops according to their photosynthetic activity (maximum LAI/NDVI in spring or summer), a multiseasonal NDVI dataset gathered from POSTEL (Pôle d'Observation des Surfaces continentales par TELédétection) was taken into account (Bicheron et al., 2008). With a spatial resolution of 300 m, it provides information about the photosynthetic activity of vegetation in a two monthly temporal resolution. The dataset can be accessed online free of charge from bimonth 6, 2004 to bimonth 3, 2006 via the POSTEL portal. This approach uses two NDVI scenes of bimonth 3 (May, June) and bimonth 4 (July, August) from the year 2005, since the different photosynthetic activities at these points in time can be used to make assumptions about the type of crop that is growing (Figure 8.4.1). Preparing the data for a change detection approach, the bimonth 4 imagery was subtracted from bimonth 3 (Figure 8.4.4). The blue coloured areas in Figure 8.4.4 indicate a phenological behaviour of crops with a photosynthetic maximum in spring while red coloured areas indicate a temporal shift of plant activity to summer. Obviously, within the area of interest,

significant distinctions in temporal change of NDVI can be made. It is striking that some regions like the northern part of the Po Valley, are clearly distinguished from others.

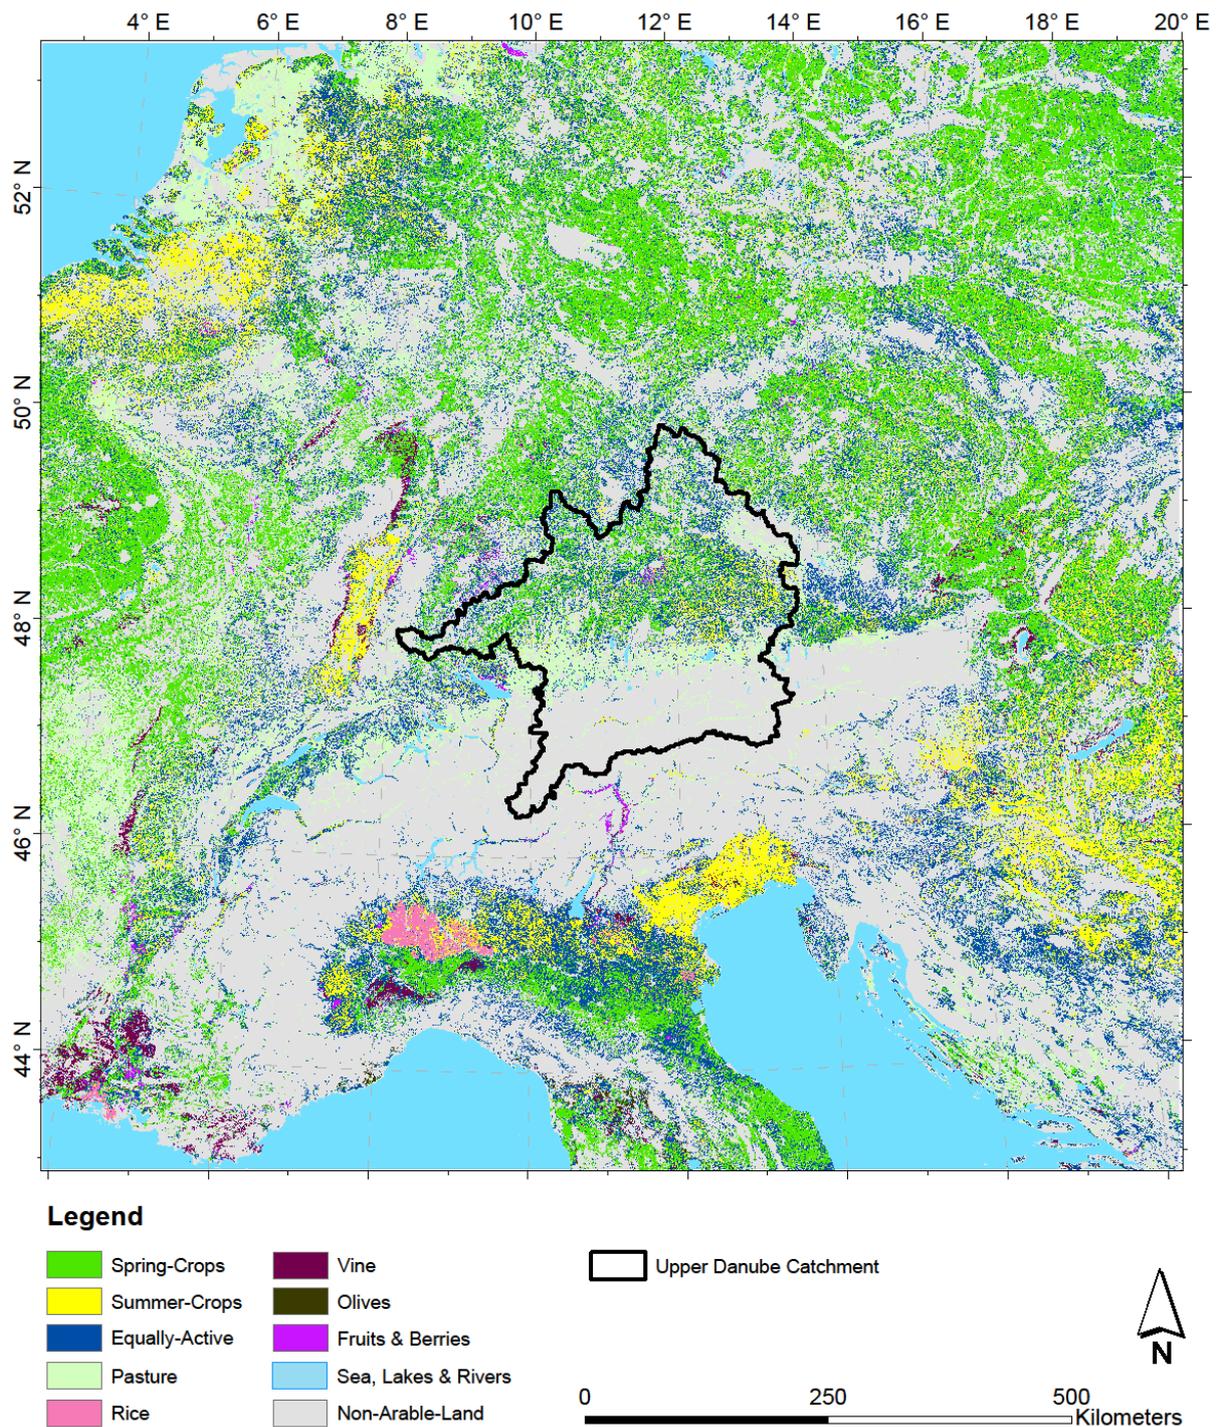

**Figure 8.4.4: Temporal change of MERIS NDVI, masked for arable land as a subtraction of Bimonth 4 with Bimonth 3.**

Using a decision tree as shown in Figure 8.4.5, the change of NDVI, masked with the area of arable land was classified into three different phenological classes.

**Figure 8.4.5: Decision tree for the differentiation of three phenological categories (spring, summer, equal) using the change signal of two MERIS NDVI images for Bimonth 3 and Bimonth 4 2005.**

The NDVI may return values between 0 and 1 for the dry land surface. Detected changes falling below 0.1 were treated as being within a range of uncertainty and thus were classified as 'equally-active'. Changes exceeding 0.1 were classified as 'spring-crops' or 'summer-crops' respectively.

**Figure 8.4.6: Phenological subclasses of arable land from CLC after splitting with MERIS NDVI.**

As a result it is possible to differentiate between the phenological classes 'spring-crops', 'summer-crops' and vegetation that does not show a change in activity within this time period, called 'equally active' (Figure 8.4.6). The denotation 'summer-crops' groups all kinds of crop plants like maize, potato, sugar beet or legumes that show a phenological behaviour with the highest rate of growth in summer and that significantly exist within the area of interest, while

'spring-crops' are e.g. winter wheat, winter barley, rape, oat or rye with highest rates of growth in spring. Regions dominated by 'summer-crops' can be recognized e.g. in the Rhine Valley (Figure 8.4.6). The Po Valley shows a separation into 'summer-crops' north and 'spring-crops' south of the Po. Along the Po River, 'equally-active' land was classified. While central Germany, Poland as well as the Czech Republic are mostly covered with 'spring-crops', Hungary, Croatia in the east but also the Netherlands and Belgium in the north-west are mainly covered by 'summer-crops'. The resulting map subsequently is used for a further statistical subdivision of these phenological-classes to specific crop types.

### ***Statistical subdivision of phenological classes***

This was done with the help of statistical information from the Statistical Office of the European Communities (EUROSTAT) for each so-called NUTS region (Nomenclature des unités territoriales statistiques) in the area of interest. The NUTS regions represent administrative regions within the countries of the European Union. The EUROSTAT dataset used for this study includes information on the 2006 acreage of different crop types for each NUTS region. The gathered classes 'spring-crops', 'summer-crops', 'equally-active' and 'pasture' (Figure 8.4.6) are subdivided with the help of the statistical dataset. The classes 'rice', 'vine' and 'olives' are already spatially located within the CLC 2000 dataset and therefore do not need to be taken into account for the statistical reclassification. A check-up showed that the sum of area of these classes agrees fairly well with the EUROSTAT statistics for each NUTS region. All vegetables of the statistics were merged with the class 'fruits & berries'. Therefore, the class label changed to 'vegetables, fruits & berries'. Among the other classes, the absolute amount of area associated to each crop type was converted into the percentage of arable land for each NUTS region. Finally, the regional distribution was based on a decision scheme as shown in Table 8.4.5. According to the priorities listed in Table 8.4.5, the first class to be distributed was winter wheat since it is the most widely spread crop type in central Europe. As winter wheat is a spring active crop type, it was evenly distributed into the class 'spring-crops' for each NUTS region. If the spring crop area derived from MERIS was too small to contain all the winter wheat area that should be distributed according to the statistics, the remaining winter wheat areas were further distributed evenly among the class 'equally-active', according to the 'Fill-up-Order' in Table 8.4.5. Following the priority of Table 8.4.5, the next crop type to be distributed was maize as it is the second most frequent land use of arable land within the area of interest.

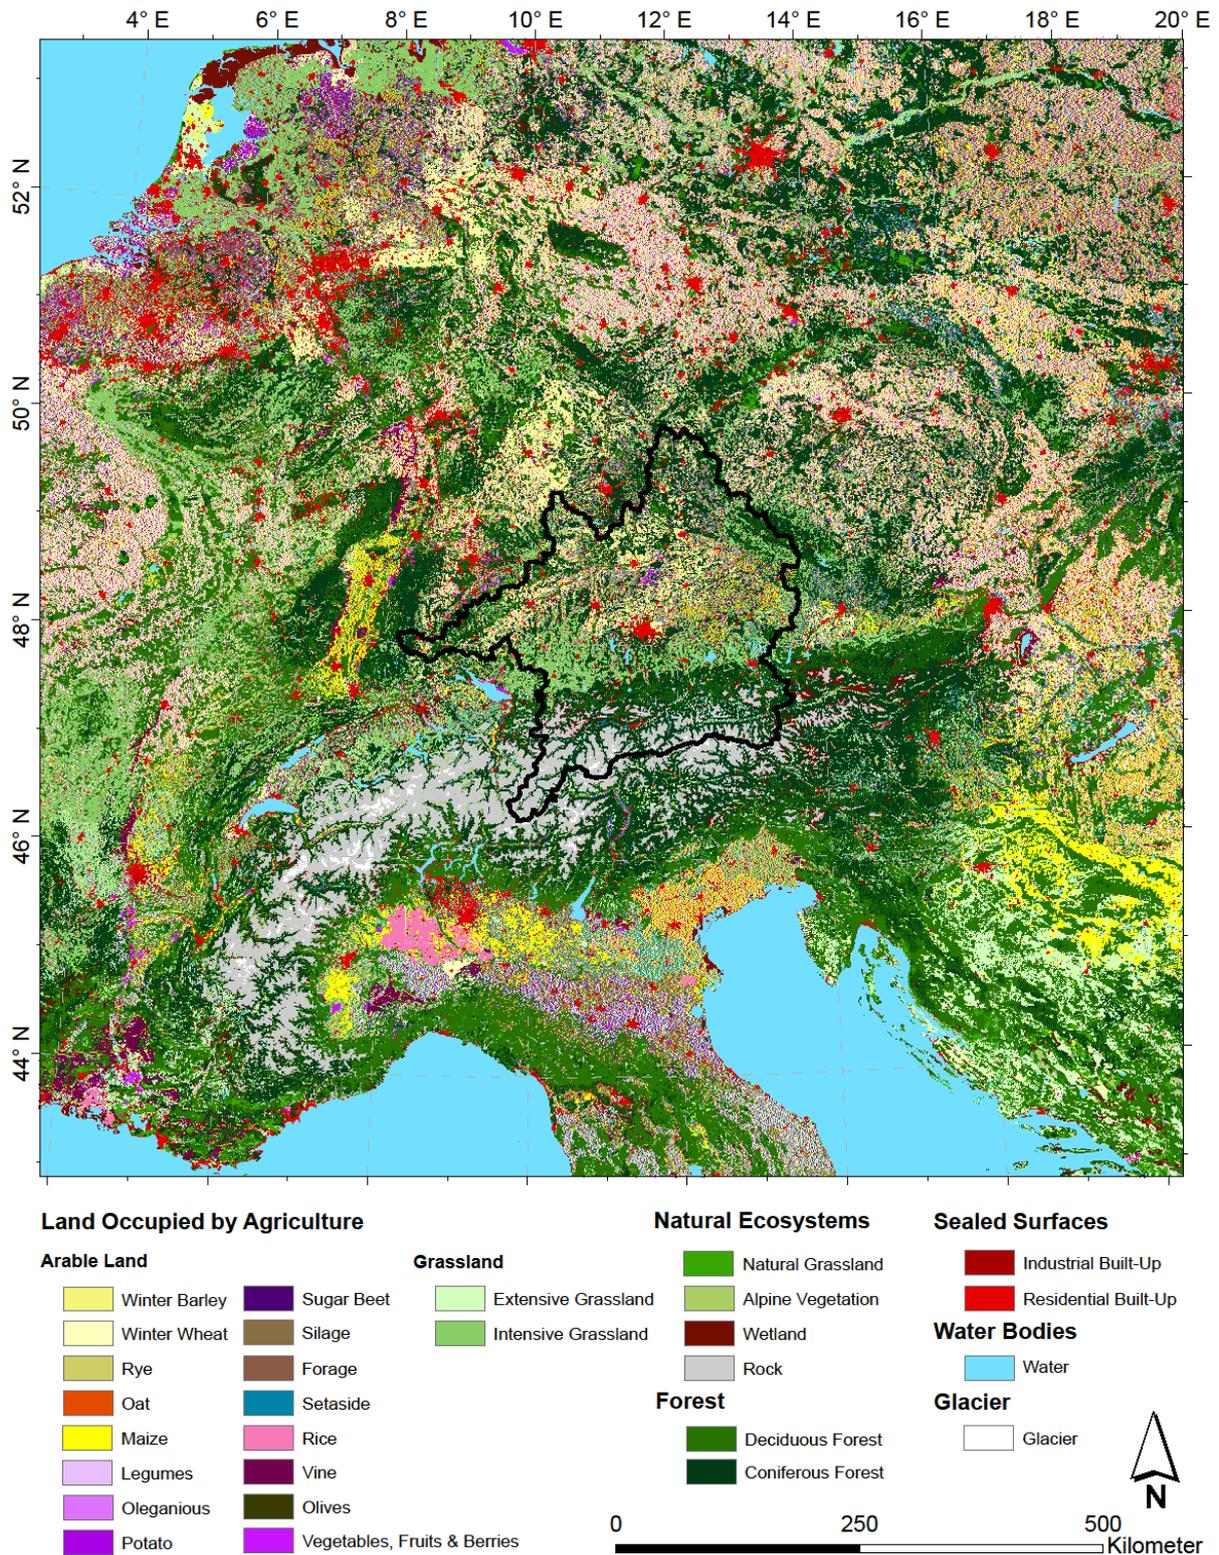

**Table 8.4.5: Priority list and 'Fill-up-Order' for the statistical reclassification of 'spring-crops', 'summer-crops' and 'equally-active' crops into 15 different types of arable land.**

<b>Priority</b>	<b>Class</b>	<b>Fill-up-Order</b>

## **Results**

### **Resulting land use/cover map**

As a result, the percentage of each individual subclass of arable land matches the statistical percentage derived from the EUROSTAT statistical data for each NUTS region. However, due to the purely statistical distribution, there is no guarantee for the correct spatial positioning of the pixels. Hence, an accuracy matrix as it is often shown to demonstrate the significance of a land use/cover classification cannot be applied at this point. Nonetheless, the likelihood for a correct placement of a pixel was increased by using the multitemporal NDVI dataset.

**Figure 8.4.7: Resulting land cover map based on CLC 2000 and CLC 1990 Switzerland and being transformed to the PROMET classification, after phenological subclasses of arable land gathered by MERIS NDVI were further statistically reclassified with the help of the EUROSTAT dataset.**

Figure 8.4.7 shows the resulting land cover map including 18 subclasses of land occupied by agriculture at a spatial resolution of 1 km. In order to allow for subscale modelling, the same

approach was applied for the generation of a 100 m land cover map using CLC (100 m) as base data. In this case, the MERIS NDVI images were resampled from 300 m to the final resolution of 100 m.

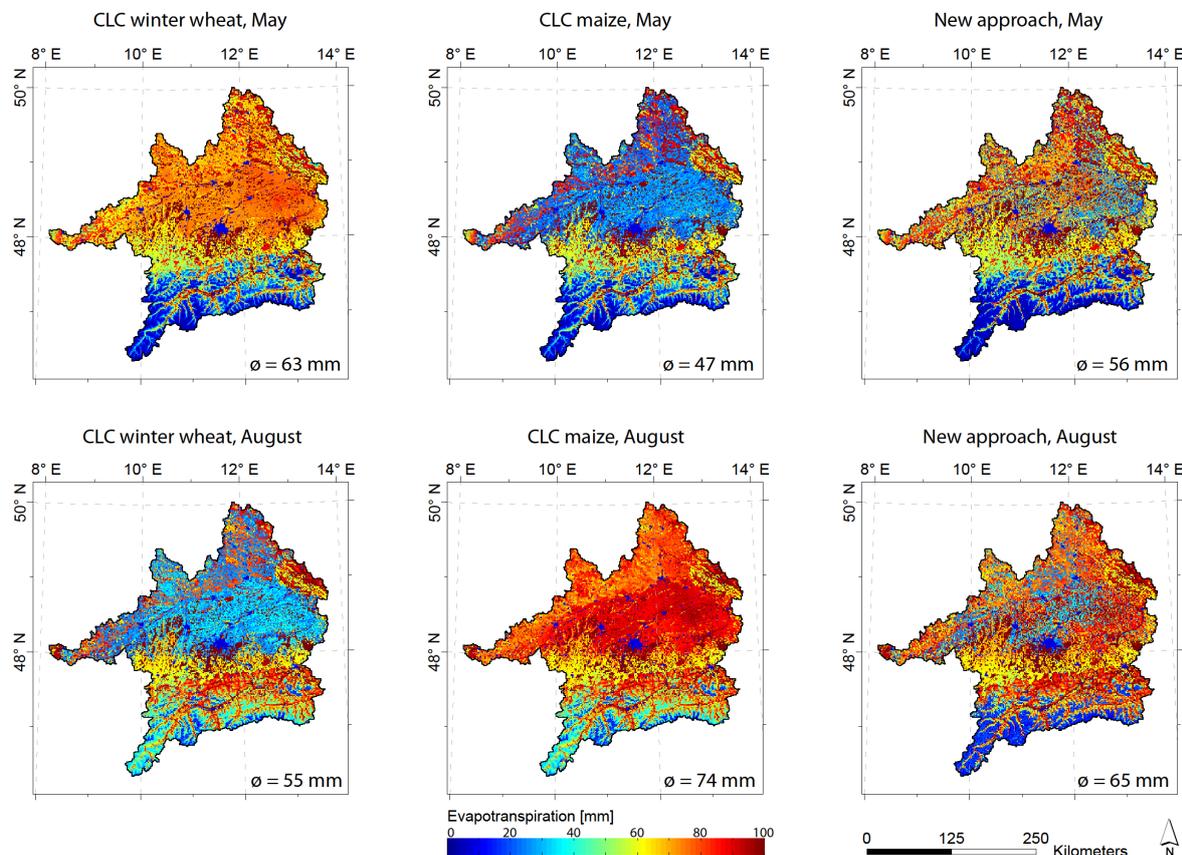

The patterns of Figure 8.4.6 still can be recognized in Figure 8.4.7 e.g. in the region of the Rhine Valley that is dominated by maize according to the statistical reclassification. This can be taken as an indication for the reliability of the NDVI approach, since the NUTS statistics match the NDVI in the Rhine Valley well (compare Figures. 8.4.6 and 8.4.7.). In addition, the segregation within the Po-Valley is reproduced in Figure 8.4.7 in comparison with Figure 8.4.6. Partly, the agricultural areas are fragmented and heterogeneous, due to the applied even distribution method. Due to a lack of the statistical data for Croatia as well as for Bosnia and Herzegovina, all 'summer-crops' in that area were reclassified to maize and all 'spring-crops' to winter wheat, while the class 'equally-active' was labelled as pasture.

### **Impact on simulated evapotranspiration**

As the new land use/cover approach is accounting for the spatial heterogeneity of arable land and thus is respecting the different phenological behaviour of different crop types, modelled evapotranspiration is expected to be improved using the new land use/cover approach. Therefore, the model PROMET (Mauser and Bach, 2009) was applied to the simulation of the hydrology of the Upper Danube catchment exemplarily, using three different land use/cover schemes as input data.

The first two land cover schemes both consisted of the reclassified CLC 2000 and CLC Switzerland neglecting the subdivision of arable land. A plant parameterization of the class 'arable land' is not possible. Only a mixed parameterization of a homogeneous class 'arable land' could handle the diversity of crops within the class 'arable land'. Nonetheless, this cannot reasonably represent reality. Therefore, all arable land was consequently reclassified to maize (CLC maize) respectively winter wheat (CLC winter wheat) since PROMET is well parameterized for the simulation of these crop types. Maize and winter wheat were assumed to represent summer (maize) and spring crops (winter wheat) respectively as these classes state two possible extremes. The third land cover scheme finally consisted of the improved land cover approach mapped in Figure 8.4.7 (New approach). Investigating the hydrological impact, the evapotranspiration was modelled with PROMET using a spatial resolution of

1 km and a temporal increment of 1 hour for the time period from 1971 – 2000. The model was driven by spatially interpolated meteorological data from 277 weather stations (Mauser and Bach, 2009).

**Figure 8.4.8: Modelled mean monthly evapotranspiration (1971-2000) in May and August with three different land use/cover classification schemes implemented in PROMET (CLC winter wheat, CLC maize and the new land use/cover approach) for the Upper Danube catchment.**

Comparing the modelled monthly mean evapotranspiration of 'CLC winter wheat' and 'CLC maize' (Figure 8.4.8) for the month of May as well as for August, a distinct behaviour in evapotranspiration due to the different phenological development of spring- and summer crops is obvious. While the 'CLC winter wheat' classification in May already shows high values of monthly evapotranspiration for the winter wheat areas of up to 70 mm, the maize classification (CLC maize) does not contribute to evapotranspiration yet (Figure 8.4.8). In August, however, the winter wheat already is harvested and therefore does not transpire anymore, while the maize transpires between 80 mm and 100 mm per month and therefore is heavily involved with the catchment evapotranspiration. This clearly demonstrates a huge impact of the land use on the simulated evapotranspiration. Regional differences of up to 80 mm per month depending on whether the land use is maize or winter wheat may occur. Only within the new land use approach, it is possible to trace spring and summer active crops

in the modelled evapotranspiration. This gives a more realistic picture of the spatial behaviour of evapotranspiration in May and August. Spatial patterns of simulated evapotranspiration for the new land use approach in Figure 8.4.8 indicate the different phenological state of spring and summer crops in May and August respectively. While spring active crops are dominating the northern part of the catchment area, summer active crops are dominating the eastern part according to the land cover distribution assumed in Figure 8.4.7. Even more, the influence of the new land use approach on the evapotranspiration is supposed to be stronger in regions where a clear majority of spring or summer crops is cultivated, such as the Upper Rhine Valley, which is clearly dominated by maize. Other studies also found significant differences in evapotranspiration and energy fluxes corresponding to different crop types using similar model approaches (Richter and Timmermans, 2009).

### **Validation of the Water Balance**

Figure 8.4.8 clearly indicates a huge impact of the land use/cover on the simulated evapotranspiration. This affects the simulated water balance in the Upper Danube catchment. In order to quantify the improvement of the new land use/cover approach, the water balance was calculated using the three land use/cover classifications 'CLC winter wheat', 'CLC maize' and the new land use approach. The resulting runoff was compared to the measured runoff volume at the outlet gauge in Achleiten. Since the Upper Danube catchment is evenly fractioned in spring and summer crops and therefore, the yearly evapotranspiration sums between the three land use classifications do not differ largely, the water balance for the whole year is supposed to be similar. Only during the growing season from May to September, the new land use approach has an impact on the amount of evapotranspiration and therefore on the water balance. Runoff formation in the Upper Danube catchment is predominantly influenced by snow cover dynamics. In order to clearly identify the improvement caused by the new land cover approach, the month of August was selected for further analysis since the influence of the snow cover was supposed to be comparably small.

**Table 8.4.6: Water balance of three PROMET simulations using the CLC winter wheat, the CLC maize and the new land use/cover approach in comparison to the measured gauge in Achleiten as mean values from 1971 - 2000 for the month of August.**

	Precipitation	Evapotranspiration	Runoff	Measured Gauge (Achleiten)
CLC winter wheat	117 mm	55 mm	62 mm	55 mm
CLC maize	117 mm	74 mm	43 mm	55 mm
New approach	117 mm	64 mm	53 mm	55 mm

The observed monthly mean precipitation in August (1971-2000) was 117 mm. PROMET returned mean monthly evapotranspiration of 55 mm (CLC winter wheat), 74 mm (CLC maize) and 64 mm (New approach) respectively. According to the water balance, this leads to mean monthly runoff values of 62 mm (CLC winter wheat), 43 mm (CLC maize) and 53 mm (New approach) respectively. Compared to the measured runoff value gathered from the outlet gauge in Achleiten (55 mm), the new approach significantly improves the model results (see Table 8.4.6).

## Conclusions

The changing characteristics of crop phenology in the course of the growing season due to differences in albedo, crop height, aerodynamic properties and leaf and stomata properties affect the mass - and energy fluxes on the land surface (Allen et al., 1998). As shown, LAI measurements clearly indicate a heterogeneous phenological behaviour of different crop types. In order to describe these effects in a physical model, a land use/cover scheme is necessary that supplies adequate heterogeneity with high spatial resolution, in combination with an accurate classification and parameterization of the plants properties. By grouping various crop types into only one mixed class of 'arable land', most available land use/cover products cannot take the heterogeneity within the different crops into account. Therefore, we developed a land cover map that uses the high resolution of the CLC classification but comprises the heterogeneity of arable land. Thus, phenological classes due to multiseasonal MERIS NDVI imagery data were compiled in order to distinguish crop types following their different phenological behaviour. Subsequently, the generated phenological classes were subdivided following statistical data from EUROSTAT for each NUTS region. The land use/cover scheme strongly affects the simulated evapotranspiration of a hydrological model. Therefore, modelling the evapotranspiration for the Upper Danube catchment with the hydrological model PROMET, the new land use approach was compared to two possible extremes: In one case, the class arable land was interpreted as pure spring crop (winter wheat), whereas in a second case the complete arable land area was assumed to represent a summer crop (maize). With the new heterogeneous land cover approach, the regional characteristics of arable crops can be addressed with a higher level of detail. Due to those improvements, the simulated monthly evapotranspiration especially in May and August shows large differences in comparison with the simulations using the two possible homogeneous classifications, especially in regions dominated by spring or summer crops respectively. The different spatial and temporal behaviour of modelled evapotranspiration again affects the water balance for the Upper Danube catchment in case of the three land use classifications. The modelled runoff was compared to measured data from the outlet gauge in Achleiten for a 30-year period from 1971 to 2000. The new land use approach could improve the model results significantly. The importance of land use/cover information is increasing when investigating the interactions between the land surface and the atmosphere (Tian et al., 2004). However, feedback effects from the land surface to the atmosphere are not considered in this study. Vegetation development and land use/cover heterogeneity have a significant influence

on climate model simulations such as predictions of surface temperature and precipitation. Thus, for the application in climate models, both the spatial and temporal distributions of vegetation are required with a high level of detail (Lu and Shuttleworth, 2002).

## **8.5. Transition to Publication II**

Publication II is introducing the bi-directionally coupling approach between the LSHM PROMET and the RCM MM5 and demonstrates the resulting effects (see Figure 8.1.1). Thereby, the high resolution land use/cover dataset, compiled in publication I is used as an essential input for the PROMET model, allowing for distinguishing a broad palette of vegetation and crops, including a variety of natural and artificial surfaces within the simulation of the land surface fluxes. A detailed comparison in publication II demonstrates the huge differences between the NOAA-LSM as the integral LSM of the RCM MM5 and the LSHM MM5. Throughout the comparison, the impact of the different physical formulations (see Appendix 12.1), different parameterizations of plants and soil, and the different spatial scales, on the offline (uncoupled from the atmospheric model) model results are investigated.

After the offline model comparison, the impacts of online (fully coupled with the atmospheric model) coupling PROMET with MM5 on the atmosphere and the land surface by feedback effects, are investigated for the model domain of Central Europe. Thereby, the different spatial behaviour of the resulting evapotranspiration within the online coupled approach is analyzed more precisely by focusing on different regions within the model domain.

The study of publication II clearly proves that the LSHM PROMET is able to provide the lower boundary conditions for the atmospheric part of MM5 within the introduced coupling approach. By allowing for feedbacks between the LSHM and MM5, both land-atmosphere and atmosphere-land matter and energy fluxes are affected by different spatial and temporal behaviour.

It is explained that, for hydrological models in general and all downstream models that are driven offline with RCM output, online coupling overcomes systematic inconsistencies that appear in the offline coupled approach. For the first time, this study quantifies these inconsistencies exemplarily for the PROMET model.

## **Abstract**

Downstream models are often used in order to study regional impacts of climate and climate change on the land surface. For this purpose, they are usually driven offline (i.e., 1-way) with results from regional climate models (RCMs). However, the offline approach does not allow for feedbacks between these models. Thereby, the land surface of the downstream model is usually completely different to the land surface which is used within the RCM. Thus, this study aims at investigating the inconsistencies that arise when driving a downstream model offline instead of interactively coupled with the RCM, due to different feedbacks from the use of different land surface models (LSM). Therefore, two physically based LSMs which developed from different disciplinary background are compared in our study: while the NOAH-LSM was developed for the use within RCMs, PROMET was originally developed to answer hydrological questions on the local to regional scale. Thereby, the models use different physical formulations on different spatial scales and different parameterizations of the same land surface processes that lead to inconsistencies when driving PROMET offline with RCM output. Processes that contribute to these inconsistencies are, as described in this study, net radiation due to land use related albedo and emissivity differences, the redistribution of this net radiation over sensible and latent heat, for example, due to different

assumptions about land use impermeability or soil hydraulic reasons caused by different plant and soil parameterizations. As a result, simulated evapotranspiration, e.g., shows considerable differences of max.  $280 \text{ mm yr}^{-1}$ . For a full interactive coupling (i.e., 2-way) between PROMET and the atmospheric part of the RCM, PROMET returns the land surface energy fluxes to the RCM and, thus, provides the lower boundary conditions for the RCM subsequently. Accordingly, the RCM responses to the replacement of the LSM with overall increased annual mean near surface air temperature (+1 K) and less annual precipitation (-56 mm) with different spatial and temporal behaviour. Finally, feedbacks can set up positive and negative effects on simulated evapotranspiration, resulting in a decrease of evapotranspiration South of the Alps a moderate increase North of the Alps. The inconsistencies are quantified and account for up to 30 % from July to September when focused to an area around Milan, Italy.

## Introduction

A multitude of studies deal with possible regional impacts of global climate change on a variety of land surface processes. These studies use the results of regional climate models (RCMs), which describe the processes in the atmosphere and at the land surface, thus, including atmosphere interactions both for oceans and land. Modelling climate, therefore, always requires an adequate representation of land surface processes within the climate model. The changing meteorological drivers are further used as input to downstream models, which determine the impacts of the simulated climate change on the processes to be investigated. Downstream models are used to analyze the impacts of climate change on a broad palette of natural and/or societal developments and vulnerability including the land surface water cycle, land use and vegetation, agricultural yield and food security, human health, energy consumption, and many more (IPCC, 2007). Thereby, they usually focus on specific thematic questions that RCMs can not or only insufficiently address and on specific regions at high spatial resolution.

Nonetheless, the complexity and heterogeneity of land surface processes and the need for a more detailed view of the land surface is a long standing discussion in atmospheric sciences (Dickinson et al., 1991; Henderson-Sellers et al., 2008). There is evidence that more advanced and robust land surface models (LSMs), which increasingly consider the spatial heterogeneity (land-use, soil, elevation) and complexity of land surface biophysical and hydrological processes in the soil-plant-atmosphere continuum on an appropriate scale will reduce the uncertainties in the current modelling of land-atmosphere processes (Essery et al., 2003; Hagemann et al., 2001; Molod and Salmun, 2002; Seth et al., 1994; Yu, 2000).

Meanwhile, hydrologists have developed empirical, conceptual and more and more physically-based land surface hydrological models (LSHMs) spanning a wide range of complexity. They include detailed descriptions of vertical and lateral soil water and energy flows, vegetation dynamics and related flow regulations, snow and ice dynamics as well as energy and mass exchange with the atmosphere, and, thereby, cover the major land surface processes in the soil-plant-atmosphere continuum. However, in contrast to LSMs designed for atmosphere applications, the atmosphere is usually considered as an exogenous driver only.

At the same time as RCMs have become capable of physically downscaling the GCMs outputs to a resolution of 50 - 10 km, LSHMs evolved from their original application in small watersheds to large basins. With the improving spatial resolution of the RCMs and the

increasing areal coverage of the LSHMs, the scales covered by the two model families tend to converge (Chen et al., 1996; Henderson-Sellers et al., 1995; Yang et al., 1998). The RCMs' output at high spatial resolution now allows downstream impact models on the local to regional scale to use the results of RCM simulations offline as model input (Figure 8.6.1a). By now, the hydrological community uses simulation results from RCMs as input for their LSHMs (Kotlarski et al., 2005). However, the LSHMs operating at the land surface usually represent land surface in a totally different manner than the LSMs used within the RCM.

Due to the different scales between impact models and RCMs and because of the huge numerical load the impacts are usually assessed with, downstream impact models are usually run offline. This means that they consider the meteorological outputs of the RCMs as exogenous input only and do not feed back to the atmosphere. However, land-atmosphere interactions are largely driven by soil moisture and soil temperature, vegetation dynamics and evapotranspiration as well as snow and ice dynamics (Fischer et al., 2007; Koster et al., 2004; Koster and Suarez, 1994; Martin, 1998; Orlowsky and Seneviratne, 2010; Pitman, 2003; Schär et al., 2004; Zeng et al., 2003). A consistent analysis of the regional impacts of climate change, therefore, would request to have the impact models directly coupled within the RCMs to be able to explicitly consider the feedbacks.

While coupling a RCM with a physically based hydrological downstream impact model offline, the model chain results in two LSMs - one within the regional climate and one within the impact model, both describing the same land surface processes (Figure 8.6.1a). However, they are not identical which leads to inconsistencies within the offline model chain. They may have their causes in different scales between the LSMs, different coverage of land surface categories, different process descriptions and different parameterizations, etc. Although these inconsistencies are hardly ever quantified, they are only justified when land-atmosphere interactions are weak.

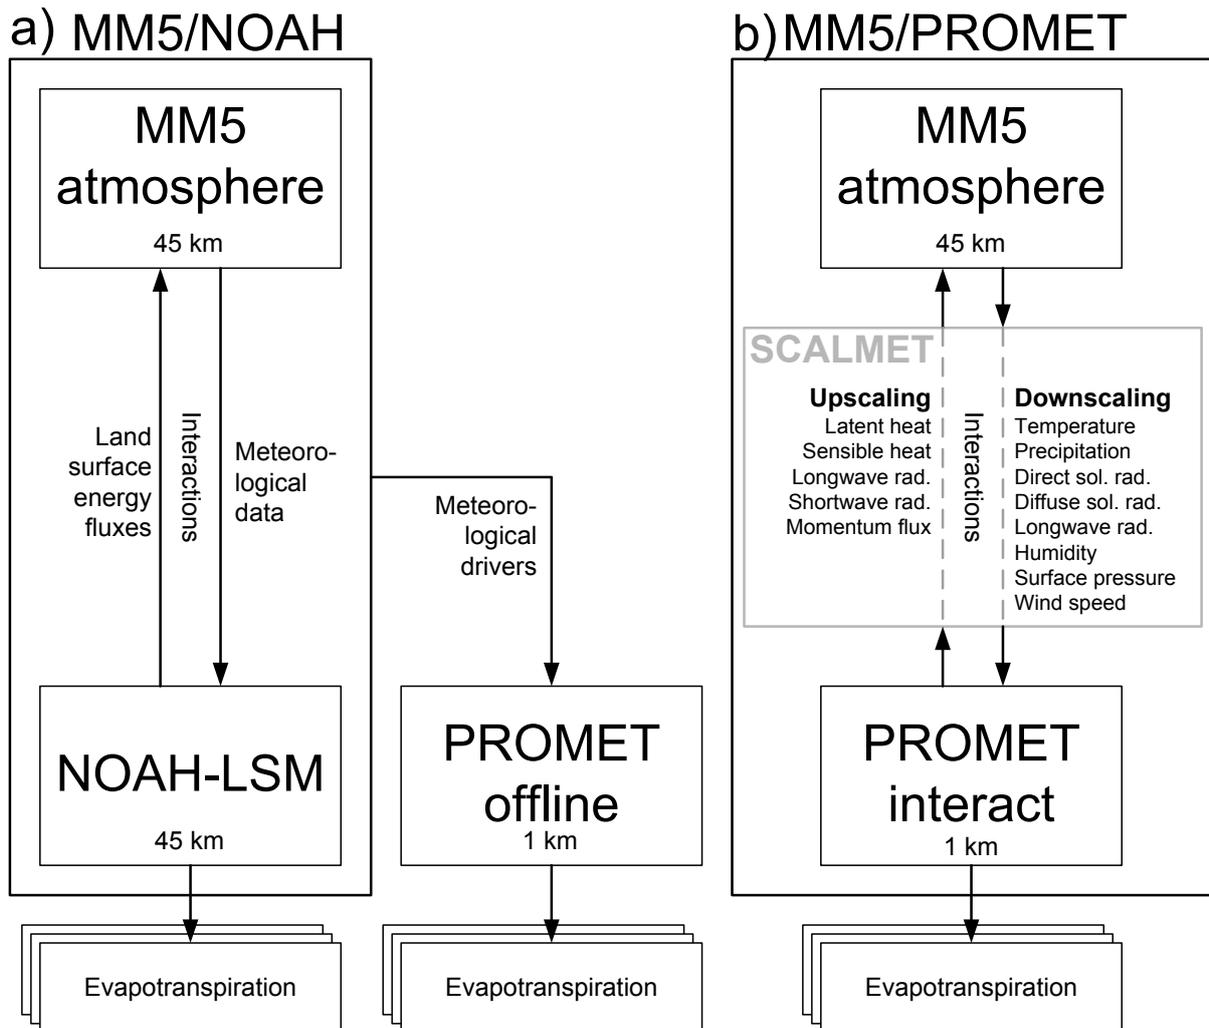

The following analysis uses a case study to compare two LSMs, one representing a LSM used within a RCM and a hydrological downstream climate impact model. It further aims at investigating the inconsistencies which arise due to different feedbacks from using the hydrological impact model offline and interactively integrated the impact model within the RCM (Figure 8.6.1b).

## Methods

### Models and setup

In order to describe the discrepancies and inconsistencies between a classical LSM used within a RCM and a LSHM, we applied the fifth-generation Mesoscale Model (MM5) (Grell et al., 1994) together with the NOAH-LSM (Chen and Dudhia, 2001a, b) at a spatial resolution of  $45 \times 45 \text{ km}^2$ . Besides, from the hydrological model family, we applied the LSHM PROMET (Mauser and Bach, 2009) at a spatial resolution of  $1 \times 1 \text{ km}^2$ . MM5 was modified and adapted to our specific simulation requirements and our model domain (Pfeiffer and Zängl, 2009; Zängl, 2002). The MM5 model domain covers most of the European continent and has a size of 79 grid-boxes in West-East and 69 grid-boxes in South-North direction with the lower left corner at ( $8.2^\circ \text{ W}$ ,  $35.6^\circ \text{ N}$ ) and the upper right corner at ( $43.2^\circ \text{ E}$ ,  $61.0^\circ \text{ N}$ ) (Figure 8.6.2) (Pfeiffer and Zängl, 2009). Lateral boundary conditions are provided 6-hourly by ECMWF ERA-40 reanalysis-data (Uppala et al., 2005). The simulation was carried out from 1 July 1995 to 31 December 1999, using a spin-up time of 6 months for all model runs. The initial soil moisture conditions were set to field capacity ( $pF = 2.3$ ) in PROMET and were initialized using ERA-40 soil moisture data [Vol-%] in NOAH.

While the NOAH-LSM was originally developed for the use in regional atmosphere applications, PROMET represents a LSHM, originally designed to study the impact of climate on hydrology on the local to regional scale. Due to the different demands on each of the models, they are supposed to differ in multiple aspects. Therefore, concerning this paper, we first conceptually compare both LSMs in terms of different scales, model physics and parameterizations. Further, evapotranspiration simulated both with the NOAH-LSM and coupled offline with PROMET (in the course of this paper named as PROMET-offline) are compared to each other (Figure 8.6.1a). In this case, both models are using the same meteorological forcing. The model results of NOAH and PROMET-offline are compared to each other in order to quantify the differences when being forced with same meteorological data.

**Figure 8.6.1: a) Principle of driving the hydrological model PROMET offline with data from the RCM MM5 within which the NOAH-LSM provides the lower boundary conditions (left). b) Interactive coupling of PROMET with the atmospheric part of MM5, thus providing the lower boundary conditions via the scaling interface SCALMET (right).**

Interactions between the downstream model and the atmospheric part of the RCM are not possible within the offline coupled approach. Downstream models which are only weakly affected by feedbacks between the land surface and the atmosphere, e.g., those who study the effect of climate change on energy demand for heating buildings, may neglect that issue. However, the hydrosphere of the land surface strongly interacts with the atmosphere. Therefore, we further interactively (often also called 2-way, bi-directionally or bilaterally) couple PROMET with the atmospheric part of MM5, thereby replacing the NOAH-LSM in MM5 with PROMET. Thus, PROMET now provides the lower boundary conditions for the atmospheric part of MM5 (in the course of this paper named as PROMET-interact) (Figure 8.6.1b). Another possible option by coupling the NOAH-LSM offline with meteorological data coming from the MM5/PROMET-interact simulation is not addressed in this study, since it is scientifically irrelevant regarding the downstream model approach.

Due to the substitution of the NOAH-LSM with PROMET, interactions between the RCM and the downstream hydrological impact model can now be taken into account. Consequently, the atmospheric part of MM5 responds to the replacement of the LSM. Therefore, we compare the temperature and precipitation output, simulated both with MM5/NOAH and with MM5/PROMET-interact, respectively. Finally, the impact of the feedbacks on simulated evapotranspiration is investigated by comparing the offline and the interactively coupled PROMET results.

A validation and comparison of the model results with measurements is beyond the scope of this paper, but will be dealt with in further studies.

## **Coupling approach**

The interactions between the land surface and the atmosphere are based on the exchange of latent and sensible heat, short and longwave radiation as well as momentum (Campbell and Norman, 2000). Since the NOAH-LSM is an integral part of MM5, it is required within the RCM to model the land surface processes at the same temporal and spatial resolution as the atmospheric model components of MM5. PROMET differs from MM5 both in temporal and spatial resolution.

For the interactive coupling of PROMET with MM5, PROMET substitutes the NOAH-LSM within the coupling domain of MM5, extending  $1170 \times 1170 \text{ km}^2$  (Figure 8.6.2). Consequently, the coarse meteorological data provided by MM5 ( $45 \times 45 \text{ km}^2$ ) has to be downscaled to the higher resolution of the land surface model ( $1 \times 1 \text{ km}^2$ ) for the coupling domain. Further, the surface fluxes simulated by PROMET at a resolution of 1 km have to be upscaled to the MM5 model resolution. This is done by applying the scaling tool SCALMET (Scaling Meteorological variables) (Marke, 2008; Marke et al., 2011). The statistical downscaling can either be used with regression based approaches (Daly et al., 2002) or empirical gradients (Liston and Elder, 2006), using elevation-dependencies in order to scale the meteorological data to the fine resolution grid. The adjustable simulation time step within PROMET, which also constitutes the exchange time step between PROMET and MM5, is set to 9 minutes in the current study. This allows PROMET to run synchronously with MM5, which uses an internal time-step of 135 seconds.

In addition to the offline downscaling approach, a 2-way (i.e., bi-directional) and, therefore, interactive coupling mode was implemented in SCALMET allowing for a linear upscaling of

the scalar surface fluxes (see Figure 8.6.2). In order to close the energy balance within the interactive coupled land-atmosphere system, the downscaling as well as the upscaling approach strictly conserves mass and energy within the scaling processes in SCALMET for each variable. Hence, no bias correction is carried out in the framework of the model runs presented in this study. Therefore, any bias of the RCM is inevitably inherited by the LSM and vice versa.

## **Study area**

The study area according to the coupling domain is situated in Central Europe and extends 1170 km North-South by 1170 km East-West including 18 European countries with the lower left corner at 3.9° E, 42.9° N and the upper right corner at 20.0° E, 53.3° N. Plains like the Po and Upper Rhine Valley, uplands like in central Germany and mountainous regions in the Alps, which mark a climatic boundary between the temperate latitudes and the Mediterranean climate, compose a complex landscape. Altitudes are ranging from the Mont Blanc in the French Alps (4810 m) to the North Sea in the North-West and the Mediterranean Sea in the South. The area is characterized by intense agriculture especially within the fertile lowlands like the Upper Rhine or the Po Valley and densely populated areas such as the Ruhr region, Berlin, or Milan.

## Comparison of modelling approaches

Since both applied models developed from different disciplinary background, the concepts behind the models vary in many aspects. While the goal of the development of the LSM was to implement an appropriate LSM for weather prediction and climate simulations, PROMET was developed for hydrological river catchment studies on the local and regional scale. A complete description of the NOAH-LSM is given by Chen and Dudhia (2001a, b) and Mitchell (2005). A comprehensive model description of PROMET can be found in Mauser and Bach (2009).

Nevertheless, both models describe the pathways of water and energy at the land surface in a physically based manner, thus conserving mass and energy and closing the energy balance at the land surface without a calibration. They are describing the same land surface processes on different scales, thereby using different formulations and parameterizations. Thus, the model results basically must be comparable and the differences between the model results must be traceable to the conceptual differences.

### Scales

One major difference is the differently applied spatial resolution. Within the GLOWA-Danube project, in which this study took place, MM5 and, thus, the NOAH-LSM was applied in climate mode with a single domain having a horizontal spatial resolution of 45 km and an integration internal time step of 135 seconds. The coarse spatial resolution was set in order to be able to simulate long time series for regional climate scenarios until the year 2100 with the available computational resources.

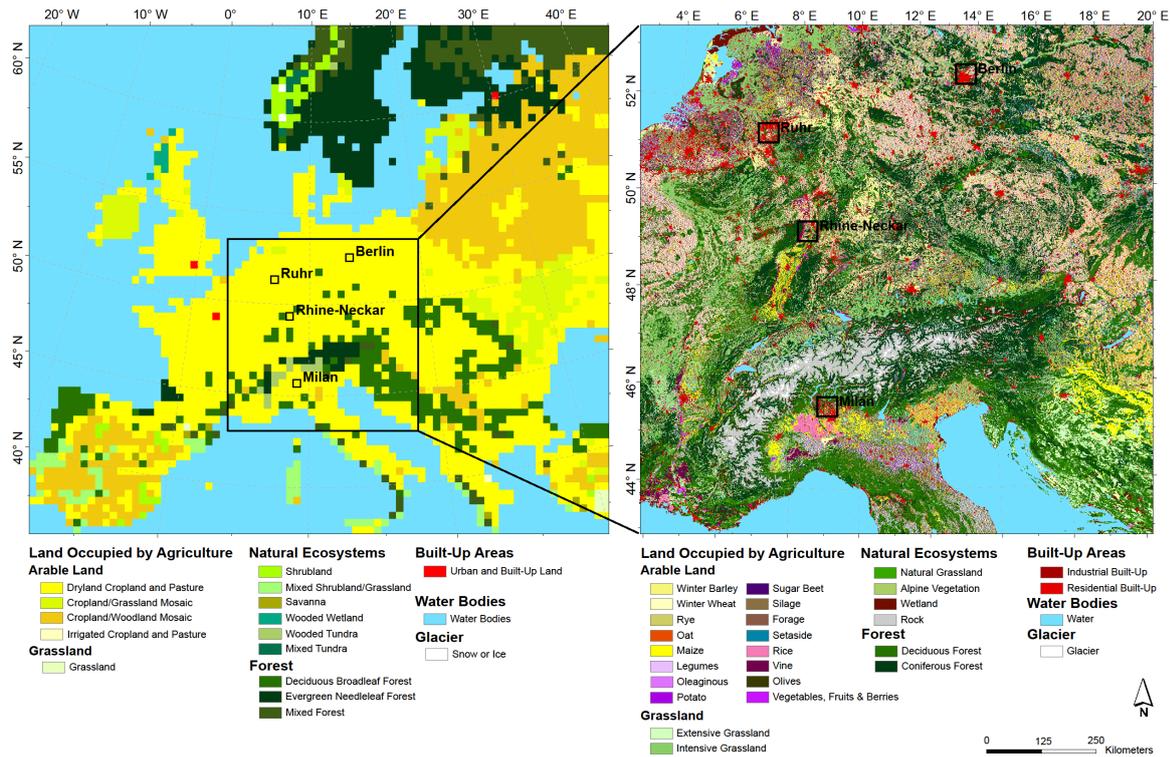

PROMET was applied at 1 km spatial resolution since it has been extensively validated in different regions in the world at 1 km spatial resolution (Mauser and Bach, 2009).

Due to the different spatial resolution, the models' underlying land-use (Figure 8.6.2), the digital elevation model (DEM) as well as the soil textures vary in spatial heterogeneity.

### Land use

The land cover information has a strong effect on albedo, emissivity and partitioning of energy and matter fluxes from the surface to the atmosphere (Ge et al., 2007). Land cover determines the type of vegetation and, thereby the seasonal development of plant phenology,

canopy structure and leaf area, which in turn, through vegetation height and leaf area index, determines the aerodynamic and evapotranspirative properties of the land surface. The combined vegetation and soil properties determine soil moisture development and the reaction of the land surface to changing fractions of latent and sensible heat fluxes influenced by vegetation water stress. Figure 8.6.2 shows the land use classifications used by NOAH and by PROMET, respectively.

**Figure 8.6.2: Land use classification of the NOAH-LSM ( $45 \times 45 \text{ km}^2$ ) for the whole MM5 model domain and the inner coupling domain (left). PROMET land use classification ( $1 \times 1 \text{ km}^2$ ) for the coupling domain with MM5.**

Impervious surfaces such as scattered urban areas are not classified in the NOAH classification, since they are small scaled and, thus, not mapped at the coarse resolution in NOAH. While most of the land is homogeneously treated as one class of mixed arable land in NOAH, PROMET separates arable land into 17 individual crop types using different crop specific parameterizations. A detailed description of the land use/cover map used in PROMET is given in Zabel et al. (2010).

For example, while for Berlin, the Ruhr Region or Milan, NOAH classifies one class representing a mixture of dryland, cropland and pasture, the  $45 \times 45$  respective upscaled PROMET pixels for each of the same area show a high share of urbanization - e.g., Berlin: 43 %, Ruhr region 55 %, Milan 37 % (Figure 8.6.2).

## **Plant parameterization**

The parameterization for each of the vegetation types in PROMET is taken from literature and remote sensing data (Bach, 1995; Mauser and Bach, 2009). Typical daily change of the dynamic plant parameters (LAI, albedo, root depth and plant height) were taken from the analysis of time series of LANDSAT images in Southern Germany in combination with extensive field measurements on typical plant stands (Mauser and Bach, 2009), thereby taking into account phenological behaviour of different stands and spatial heterogeneity (Zabel et al., 2010).

On the other hand, MM5 uses monthly values of green vegetation fraction (also known as Fcover) for each grid cell at the model's spatial resolution in order to allow for seasonal phenological behaviour of vegetation. The green vegetation fraction is derived from remote-sensing NDVI data and accordingly is also used within the NOAH-LSM to control the degree of urbanization and impervious surfaces for each grid cell. Due to known problems in NDVI scaling (Bach and Verhoef, 2003; Gutman and Ignatov, 1997; Richter and Timmermans, 2009), vegetation fraction was generally decreased by 30 percent which helped to improve the simulation of summertime near surface temperature substantially (Pfeiffer and Zängl, 2009).

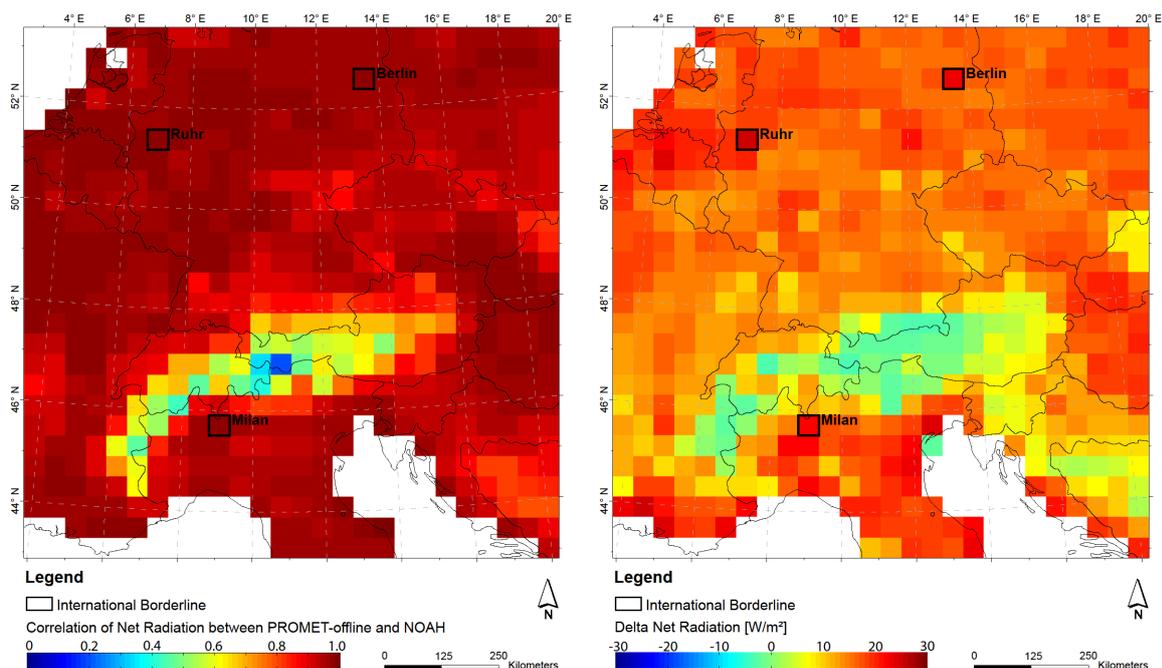

## **Soil water hydraulic and plant physiology**

Besides different underlying soil textures, the models use different physical approaches to describe the pathway of water through the soil and the plant into the atmosphere. Here, PROMET uses a more comprehensive approach, following Baldocchi et al. (1987) and Jarvis (1976), taking more soil and plant specific parameters into account. NOAH uses soil specific water contents [Vol-%] to parameterize wilting point, saturation and field capacity for calculating plant transpiration, while PROMET calculates soil water content from soil water potential and takes plant specific functions of leaf water potential into account, including a functional dependence between stomatal conductance and plant suction when calculating plant transpiration.

## Results and discussion

### Comparing NOAH and PROMET-offline

The offline coupled model approach results in two LSMs, namely the NOAH-LSM and PROMET. The differences between the two models result in different partitioning of latent and sensible heat, while incoming solar radiation, temperature and precipitation are the same for both models in offline configuration (see Figure 8.6.1a). As a result, net radiation shows a high temporal correlation between PROMET and NOAH, except for Alpine areas (Figure 8.6.3). Here, large differences in snow cover affect shortwave reflection and, thus, net radiation. Nevertheless, the PROMET net radiation in the remaining domain is higher than the NOAH net radiation (Figure 8.6.3), due to different land surface properties in terms of emissivity and albedo. Overall, more energy is available at the PROMET land surface (Figure 8.6.3).

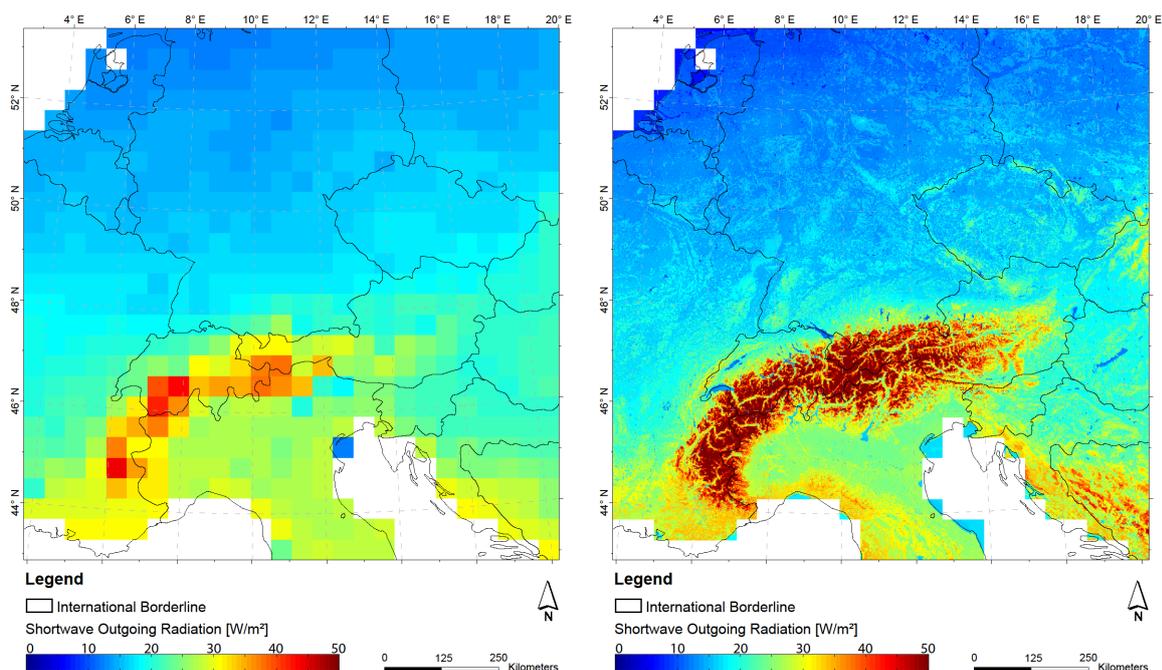

**Figure 8.6.3: Correlation ( $r$ ) of net radiation between PROMET-offline and NOAH for daily mean values (left) and difference plot of annual mean net radiation between PROMET-offline and the NOAH-LSM, scaled to the MM5 spatial resolution (right).**

While albedo is handled as a prognostic variable in both LSMs, snow cover is less dominant in the Alpine regions in the NOAH simulation due to the use of different snow modules and lower altitudes in mountainous regions caused by scale issues. Due to the higher spatial resolution in PROMET, spatial heterogeneity - especially in mountainous regions can be captured more realistically. Thus, not only snow processes, but also radiation processes can be

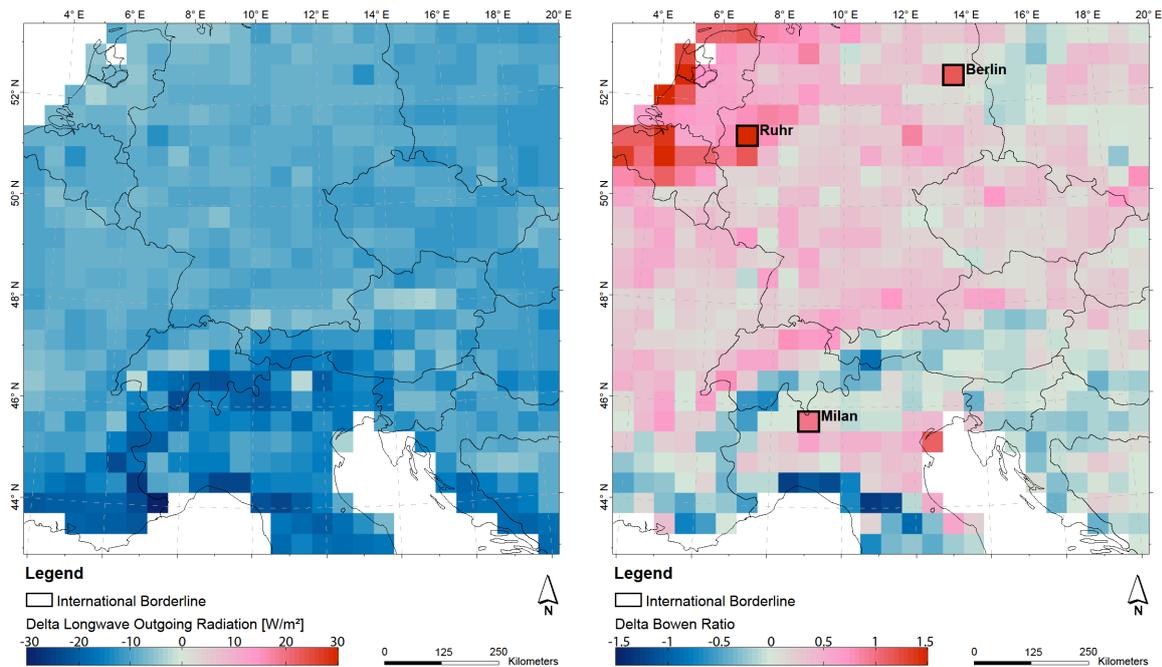

calculated with higher spatial and process detail considering, e.g., aspect, slope and altitude more accurately.

Consequently, shortwave reflection increased mainly in the Alpine part of the model domain (Figure 8.6.4), reducing net radiation in winter and spring in the PROMET simulation, while net radiation is increased in the summer months, when the snowpack has melted in mountainous regions.

**Figure 8.6.4: Annual mean shortwave reflection [ $\text{W m}^{-2}$ ] (1 January 1996 - 31 December 1999) of the NOAH-LSM (left) and PROMET-offline (right).**

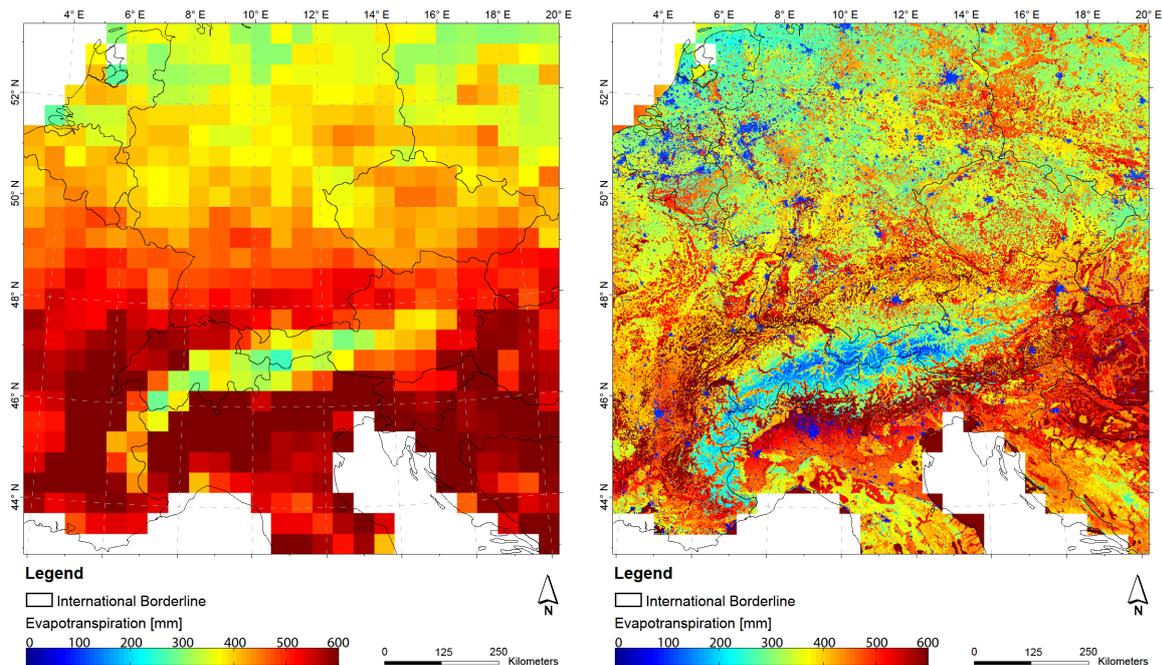

The higher net radiation in the PROMET simulation in the non-alpine areas mainly is due to differently assumed emissivities of the land surfaces, resulting in overall lower emissivity and, therefore, lower longwave outgoing radiation in the PROMET simulation (Figure 8.6.5, left).

**Figure 8.6.5: Difference plot of annual mean longwave outgoing radiation between PROMET-offline and the NOAH-LSM (left) and difference plot of annual mean Bowen ratio between PROMET-offline and the NOAH-LSM (right), each scaled to the MM5 spatial resolution.**

Further, the different portioning of the available energy at the land surface into latent and sensible heat is shown in Figure 8.6.5 (right) by subtracting the annual mean Bowen ratio. Finally, more available energy at the land surface is proportionally given more into sensible than into latent heat in the PROMET simulation, where finally the Bowen ratio remarkably increased in areas with high share of urbanization (Figure 8.6.5). The degree of urbanization shows a correlation of  $r = 0.71$  with the difference plot of the Bowen ratio.

Figure 8.6.6 compares the annual mean evapotranspiration from 1996-1999 simulated by the NOAH-LSM (left) and by the offline PROMET approach (right). Regarding the hydrological context of this paper, latent heat is shown as evapotranspiration in [mm].

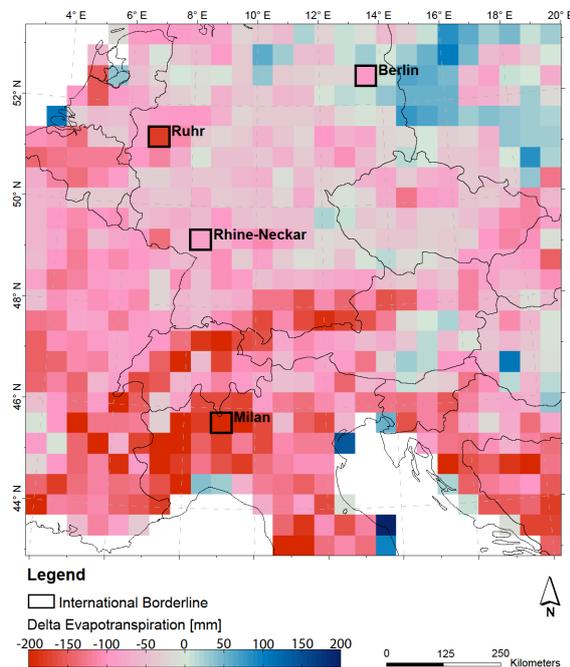

**Figure 8.6.6: Annual mean evapotranspiration of NOAH-LSM (left) and PROMET-offline (right)**

Overall, the NOAH-LSM simulation shows an annual mean evapotranspiration of 469 mm and PROMET-offline 397 mm respectively. The remarkable mean difference of more than 70 mm for the area average is diversely spatially distributed and has several reasons that we further aim to investigate.

Basically, both models show a north-to-south gradient of evapotranspiration and lower values in the Alpine region, which corresponds to the prevailing climate conditions. Daily mean values of the model domain are highly correlated between the models ( $R^2 = 0.94$ ). The most obvious difference is the spatial heterogeneity related to the spatial resolution applied to each model. The PROMET-offline evapotranspiration allows for recognising small-scale spatial patterns such as Alpine valleys with high contrasts to its surroundings and forested areas with high evapotranspiration as can be found e.g., in the Black Forest (approx. 48.5° N 8.3° E). While the PROMET land-use data set includes a number of impervious surfaces (residential or industrial areas and rocks) that do not contribute to transpiration and, therefore, reduce annual mean evapotranspiration, the NOAH underlying land-use dataset accounts only for a small number of land-use classes and mainly implements cropland in the model domain (Figure 8.6.2). The effect of different land-uses and impervious surfaces in PROMET becomes especially apparent in large urban areas such as Berlin or the extended Ruhr region as well as in rocky Alpine areas (Figure 8.6.6). In order to compare the model results on the

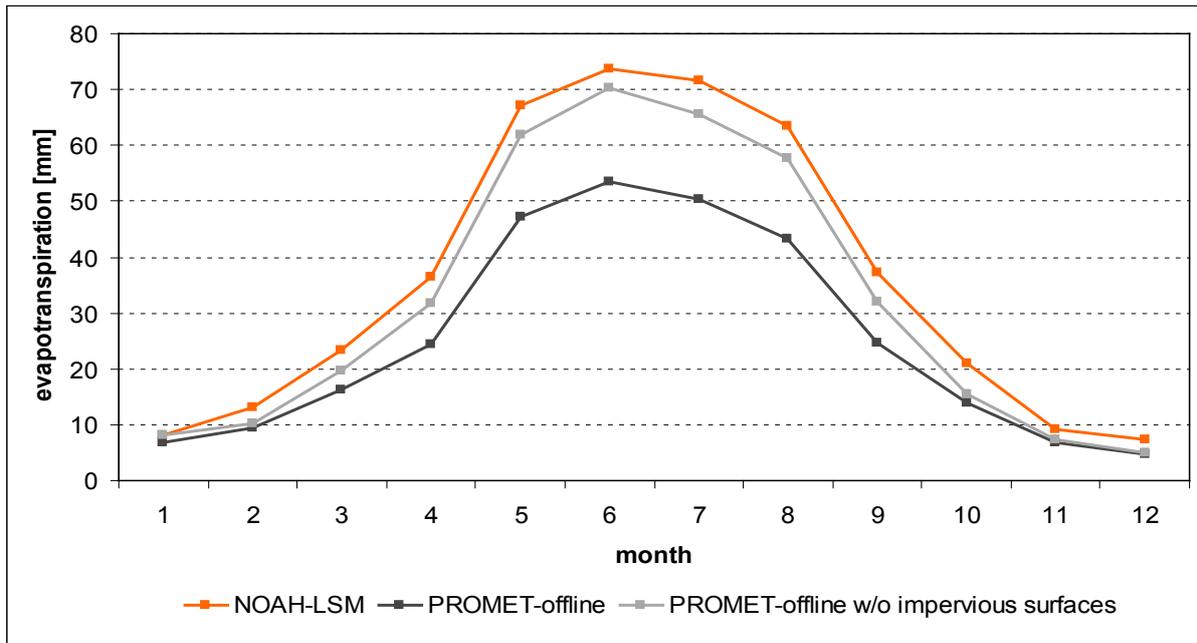

same spatial scale, we aggregated the PROMET-offline result to the spatial resolution of  $45 \times 45 \text{ km}^2$  and finally subtracted it from the NOAH evapotranspiration (Figure 8.6.7).

**Figure 8.6.7: Difference plot between PROMET-offline and NOAH-LSM showing the annual mean evapotranspiration.**

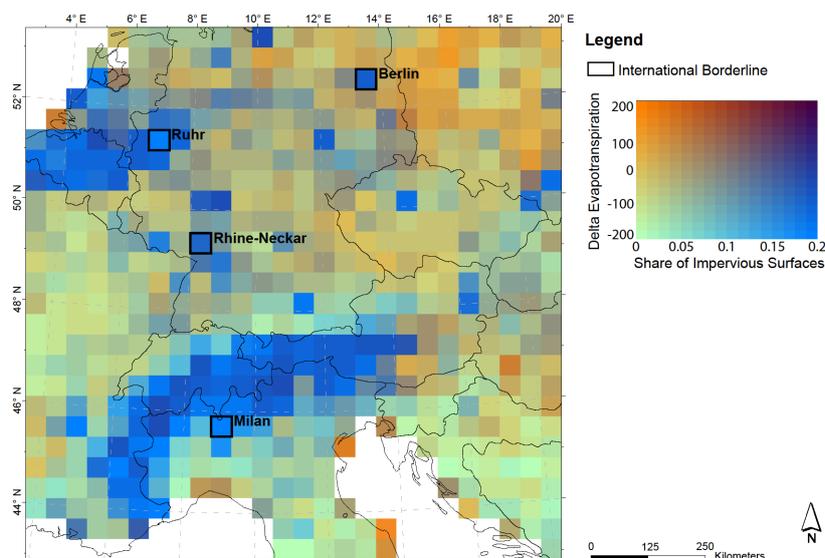

The highest difference of evapotranspiration can be found at the Milan pixel. Here, evapotranspiration is reduced by 283 mm from 707 mm (NOAH) to 424 mm (PROMET-offline).

Further, Figure 8.6.8 compares the models' evapotranspiration by assuming a similar land use in both models. For this purpose, impermeable areas are ignored when upscaling the  $1 \times 1 \text{ km}^2$  PROMET evapotranspiration to the MM5 spatial resolution. Figure 8.6.8 shows the monthly mean values only for pixels with a share of impermeable area of at least 20 % in the upscaled PROMET land use classification. Thereby, different assumptions in the LSMs' underlying land use classification in terms of impervious surfaces result in great differences in summer (up to  $21 \text{ mm month}^{-1}$  in July) and small differences in winter ( $1 \text{ mm month}^{-1}$  in January). By neglecting impervious surfaces, the prominent annual gap of  $130 \text{ mm year}^{-1}$  is reduced to  $46 \text{ mm year}^{-1}$  and the difference in July is reduced to  $6 \text{ mm month}^{-1}$  (Figure 8.6.8).

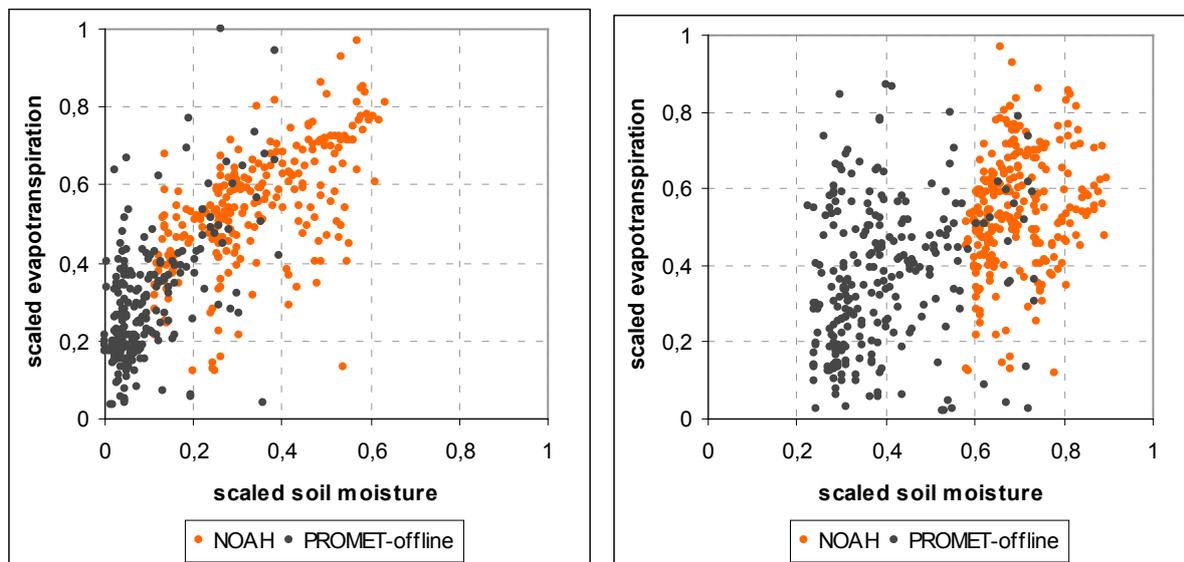

**Figure 8.6.8: Monthly mean evapotranspiration from 1996 - 1999 simulated by the NOAH-LSM and PROMET-offline for pixels, dominated by impermeable area (share > 20 %) in the upscaled PROMET land use. The PROMET-offline results are shown for all corresponding PROMET-offline pixels as well as for vegetated pixels only, neglecting impervious surfaces.**

For a spatially differentiated consideration of the impact of impermeable areas for the coupling domain, Figure 8.6.9 shows the difference of simulated evapotranspiration between PROMET-offline and NOAH versus the upscaled share of impermeable land in the PROMET land use classification, illustrated with a bivariate colour map (Teuling et al., 2011).

**Figure 8.6.9: Upscaled share of impervious area of the PROMET land use versus the difference of evapotranspiration between PROMET-offline and NOAH, illustrated with a bivariate colour map (Teuling et al., 2011).**

Another important aspect contributing to inconsistencies are due to different soil hydraulics, affecting soil moisture and, therefore, soil evaporation and plants transpiration. The functional dependence between soil moisture of the third soil layer and evapotranspiration for the Milan and Rhine-Neckar vegetated pixels for daily values in July and August is shown in Figure 8.6.10 for each model. Scaled between saturation and wilting point, PROMET operates in a drier part of the sensitivity curve, thereby more restricting evapotranspiration than the NOAH-LSM (Figure 8.6.10). PROMET reacts more sensitive to increasing soil suction and decreasing soil moisture, respectively. While the wilting point is never reached in the Rhine-Neckar area, it is already reached on several days in the PROMET-offline simulation from July to August in the Milan area (Figure 8.6.10, left). The soil layer thickness of the third soil layer is 1 m in both models, reaching from 1 to 2 m in the NOAH-LSM and from 0.5 to 1.5 m in PROMET, respectively.

**Figure 8.6.10: Daily mean evapotranspiration (normalized by maximum) plotted against soil moisture of the third soil layer (scaled between wilting point and saturation) for the NOAH-LSM and PROMET-offline, showing the vegetated pixels of the Milan area (left) and the Rhine-Neckar area (right) for July and August (1996-1999).**

### Quantification of feedbacks using PROMET-interact

The simulated latent and sensible heat between the NOAH-LSM and PROMET-offline, as showed differ both in spatial and temporal manner. When using PROMET instead of NOAH within MM5, the response of the atmosphere to the changed land surface fluxes now result in feedbacks that in turn affect the land surface energy fluxes. Thus, the inconsistencies within the offline coupling approach due to neglecting those feedbacks are quantified. Therefore, PROMET is now interactively coupled with MM5, thereby substituting the NOAH-LSM and

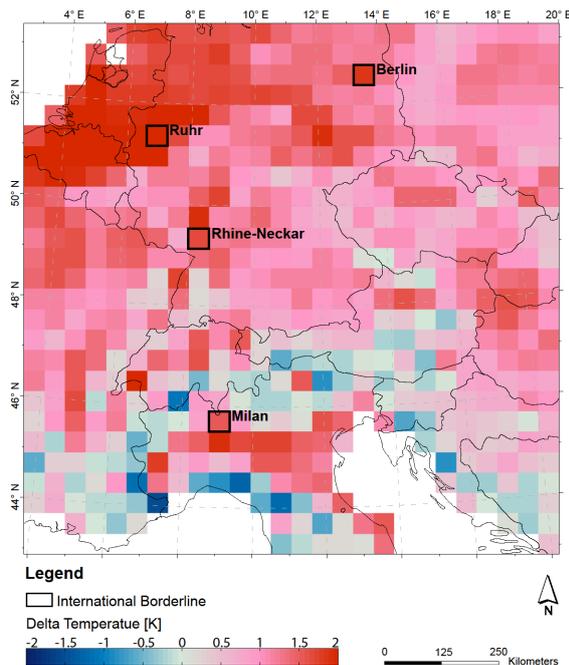

finally providing the lower boundary conditions for the MM5 atmosphere (Figure 8.6.1b). Energy conservation is guaranteed within the interactively coupled system. The feedbacks can amplify or damp an initial perturbation to the system. As a result, a new equilibrium between the land surface and the atmosphere establishes and, therefore, changes the energy fluxes in both directions. This chapter first describes the responses of the MM5 atmosphere triggered by the replacement of the LSM. Finally, the impact of feedbacks on the interactively coupled PROMET (PROMET-interact) evapotranspiration is investigated and compared against the PROMET-offline simulation.

### ***Air temperature***

Figure 8.6.11 compares the annual mean near surface air temperature between the MM5 simulation either using the NOAH-LSM or PROMET-interact. While the mean temperature over the coupling domain is 9.4° C in the MM5/PROMET-interact simulation, it is 8.5° C in the MM5/NOAH simulation. Despite the replacement of the NOAH-LSM, still a similar temperature can be reproduced within the MM5/PROMET-interact simulation with regional differences.

A higher net radiation in the MM5/PROMET-interact simulation than in the MM5/NOAH simulation as well as less evapotranspiration and, thus, less evaporative cooling result in mutually dependent higher near surface air temperature in the MM5/PROMET-interact simulation, except for mountainous regions. Here, snow cover plays a prominent role in the PROMET simulation, affecting sensible heat particularly in spring, when available energy is put into snow melt in the PROMET simulation, while energy is put into sensible heat resulting in increasing near surface air temperature in the NOAH simulation. Possible reasons for the different snow cover may be the use of different snow modules and scale issues due to different underlying DEMs.

The MM5 atmospheric model responses to the replacement of the NOAH-LSM with PROMET with higher temperatures by up to 2.4 K (in the Ruhr region) as shown in Figure 8.6.11.

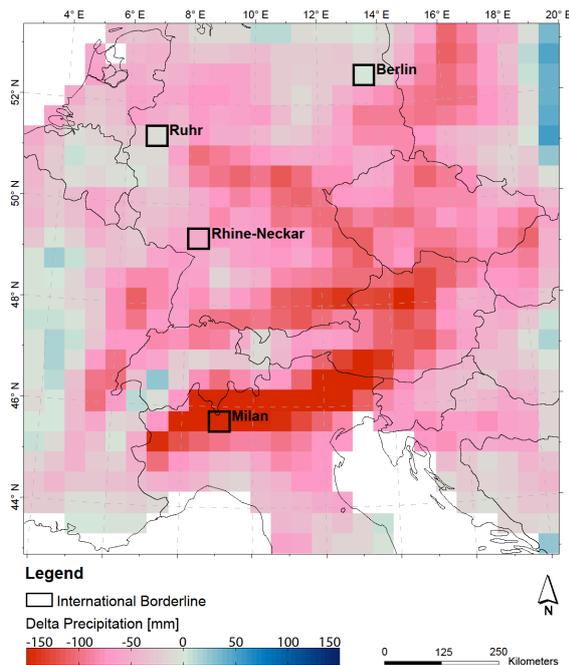

**Figure 8.6.11: Subtraction image (MM5/PROMET-interact - MM5/NOAH) of the annual mean near surface air temperature [K] (1 January 1996 - 31 December 1999).**

While the annual mean near surface air temperature for the PROMET Milan pixels is 1.6 K warmer ( $14.2^{\circ}\text{C}$ ) than the MM5/NOAH simulation ( $12.6^{\circ}\text{C}$ ), maximum differences (3.3 K) appear in June, while in winter, when energy assumption at the land surface is low, temperature is hardly affected by feedbacks.

### **Precipitation**

Besides temperature, precipitation is another parameter strongly interacting with the land surface and having large hydrological impacts on LSHMs. The changed lower boundary conditions in the PROMET-interact simulation result in less annual precipitation amounts, especially South of the Alps (Figure 8.6.12). While the annual precipitation amount over the simulation area is 830 mm in the MM5/PROMET-interact simulation, it is 886 mm in the MM5/NOAH simulation. The spatial patterns of annual precipitation amounts between MM5/NOAH and MM5/PROMET-interact simulations are almost the same. However, total precipitation amounts decrease mostly North and South of the Alps and in the Po-Valley by up to 213 mm (Figure 8.6.12).

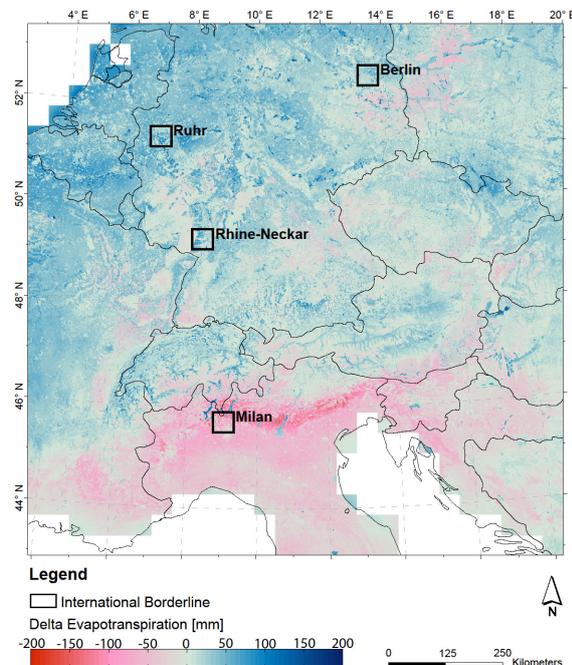

**Figure 8.6.12: Subtraction image (MM5/PROMET-interact - MM5/NOAH) of the annual precipitation [mm] (1 January 1996 - 31 December 1999).**

Maximum differences compared to the MM5/NOAH simulation occur mainly in August, when almost 50 mm less precipitation is simulated for the Milan area by using the PROMET-interact land surface within MM5. Concerning the Milan pixels, the annual precipitation differs by 164 mm which is about 15 %. The decrease of total precipitation is difficult to diagnose. It is mainly based on a decrease of convective precipitation in summer. The different portioning of energy into sensible and latent heat overall results in an increase of sensible heat in the PROMET simulation, except for mountainous areas in winter and spring due to snow cover. With increasing sensible heat flux, the planetary boundary layer height is increasing which results in dryer air masses. As a result, cloud fraction and convection are inhibited and, thus, convective precipitation is decreasing especially in summer.

### ***Evapotranspiration***

By allowing for feedbacks between the high resolution PROMET land surface and the MM5 atmosphere, the land surface in turn is affected by the changed atmospheric conditions. The impact of these feedback effects on evapotranspiration is shown in Figure 8.6.13, thereby quantifying the inconsistencies between the offline and interactive coupling approach. Overall, the annual PROMET-interact evapotranspiration (405 mm) is a little higher than in the annual PROMET-offline simulation (397 mm).

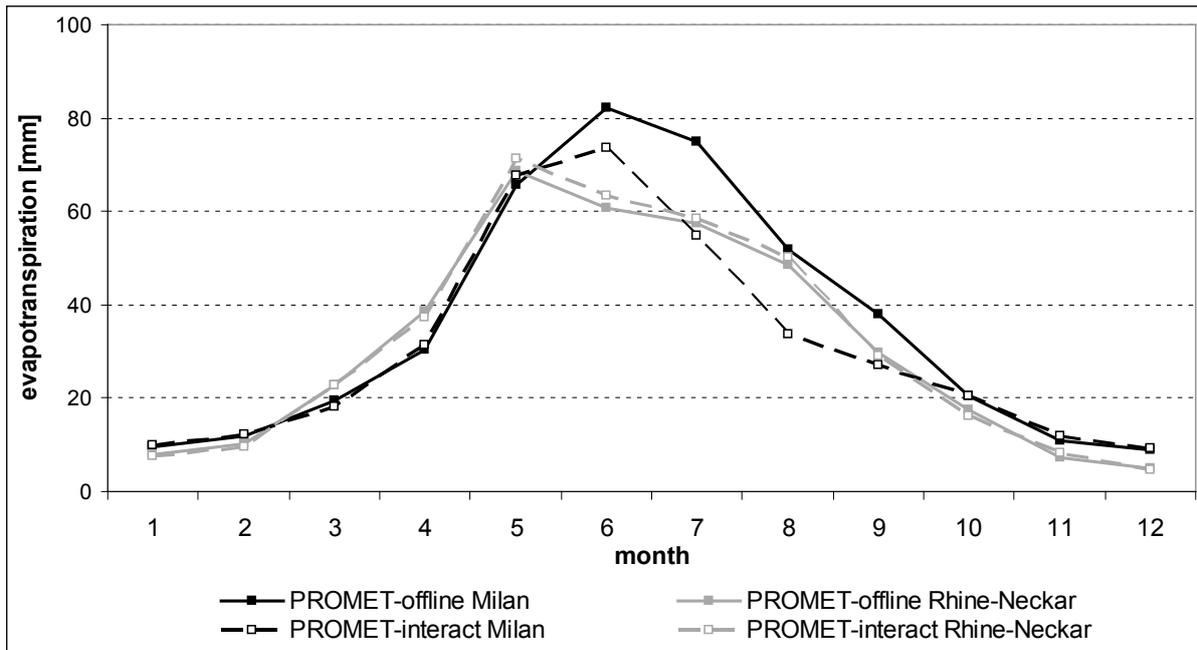

However, a more detailed spatial analysis shows remarkably smaller annual evapotranspiration rates in the Mediterranean area South of the Alps while annual evapotranspiration rates slightly increased North of the Alps (Figure 8.6.13). The highest impact of the feedbacks on evapotranspiration can be found in the Northern part of Italy, where evapotranspiration rates decreased by up to 150 mm due to dryer conditions.

**Figure 8.6.13: Subtraction image of PROMET-interact and PROMET-offline simulation for annual mean evapotranspiration ( $1 \times 1 \text{ km}^2$ ).**

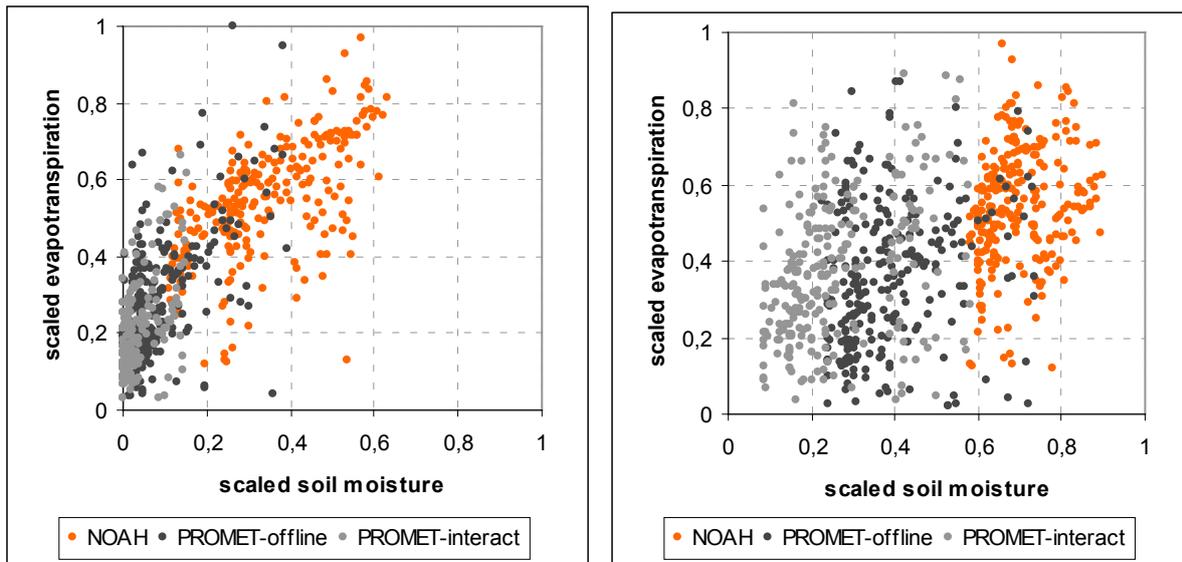

For the Milan pixels, the annual distinction is approx. 55 mm which is 13 % of the annual evapotranspiration. The inconsistencies of the offline coupling approach are most relevant in the summer months, when PROMET-interact shows decreased evapotranspiration rates, e.g., in July of up to 20 mm (27 %), while in the winter months evapotranspiration is hardly affected by the feedback mechanisms (Figure 8.6.14). When focusing on the Milan region, evapotranspiration decreased by 30 % from July to September while at the same time temperature increased by 2.7 K and precipitation decreased by 37 %.

North of the Alps as exemplarily shown for the Rhine Neckar area, annual evapotranspiration slightly increased by  $4 \text{ mm year}^{-1}$  (1.9 %). Thereby, the moderate increase mainly occurred from Mai to August and accounted for 3.2 % (2 mm) (Figure 8.6.14).

**Figure 8.6.14: Monthly evapotranspiration rates [mm] (1 January 1996 - 31 December 1999) of PROMET-offline simulation and PROMET-interact simulation exemplarily for the Milan and Rhine-Neckar pixels.**

According to Figure 8.6.10, Figure 8.6.15 now shows the degree to which the soil moisture-evapotranspiration interaction is responsible for the sign of the feedback. For the Milan area PROMET-interact now operates in a yet drier regime. While plants' water suction already reached the wilting point in PROMET-offline simulations on several days (Figure 8.6.10), feedback effects in the PROMET-interact simulations now result in an even drier soil where soil moisture is closer to the wilting point from July to August (Figure 8.6.15). This results in a higher level of plants' water-stress, restricting transpiration more. North of the Alps, exemplarily shown for the Rhine-Neckar area, where precipitation is also reduced upon implementing PROMET into MM5, PROMET-interact also operates in a yet drier regime, however, far away from reaching the wilting point (Figure 8.6.15). Thus, still enough soil water is available for plant transpiration and evaporation. Therefore, the feedbacks - especially the increased air temperature and radiation have predominantly positive effects on transpiration here.

**Figure 8.6.15:** Daily mean evapotranspiration (normalized by maximum) plotted against soil moisture of the third soil layer (scaled between wilting point and saturation) showing the PROMET-interact simulation in comparison to the PROMET-offline and NOAH results for the vegetated pixels of the Milan area (left) and the Rhine-Neckar area (right) for July and August (1996-1999).

## Conclusions

Offline driving a LSM with RCM output can lead to inconsistencies since feedbacks between the offline driven LSM and the RCM are not taken into account. The study has shown that considerable discrepancies occur between LSMs used within RCMs and downstream climate impact models. The different scales, parameterizations and formulations describing identical land surface processes in the NOAH-LSM, used within the RCM MM5, and the downstream hydrological model PROMET contribute to the inconsistencies. Consequently, net radiation was higher in the PROMET-offline simulation due to different albedo and emissivity settings. The different redistribution of this net radiation into sensible and latent heat resulted in an overall higher Bowen ratio due to e.g., more impermeable areas (such as urban areas) in the PROMET land use while the NOAH-LSM assumes the land surface to rather homogeneously consist of arable land for the coupling domain. Finally, different soil hydraulics due to different soil/plant parameterizations and different physical formulations lead to considerable hydrological differences which resulted in lower soil moisture and lower evapotranspiration.

By coupling PROMET interactively with the RCM MM5, thereby substituting the NOAH-LSM, PROMET provides the lower boundary conditions to the atmospheric part of MM5. Subsequently, the scaling interface SCALMET closes the scale gap between the models and ensures mass- and energy conservation within the down- and the upscaling of linear and nonlinear energy fluxes. Consequently, the atmosphere responded to the replacement of the LSM with increased annual air temperatures by up to 2 K and decreased annual precipitation by up to 213 mm mainly due to less convection in summer.

Finally, by comparing the offline driven and the interactive simulation, we were able to quantify the inconsistencies that occur when neglecting the feedbacks. The study has shown that the inconsistencies that arise when using PROMET offline instead of interactively coupled with MM5 are strong (up to 150 mm year<sup>-1</sup>) and, therefore, may not be neglected. Further, we demonstrated that these inconsistencies can affect evapotranspiration positively as well as negatively, depending on the prevailing hydrological conditions. The temperature increase and precipitation decrease led to drier conditions in the interactively coupled simulation. As a result, evapotranspiration decreased in regions mainly South of the Alps with already dry conditions in summer, where soil moisture was close to the wilting point. Thereby, evapotranspiration decreased by 30 % from June to September, e.g., for the Milan area. North of the Alps, however, the level of soil moisture was far away from reaching the wilting point due to more humid conditions than in the Mediterranean area. The feedbacks

affected evapotranspiration positively here, due to increased temperature and more radiation. Although precipitation decreased, still enough soil water was available for plant transpiration and evaporation. The impact of the feedbacks on evapotranspiration was almost negligible in winter but considerably high in the summer months, when energy conversion at the land surface is high, finally resulting in greater feedbacks.

Further studies will compare the offline and interactive coupling approach with observation data for annual, monthly, and diurnal time series.

## **Acknowledgements**

The research described in this paper was carried out at the Department of Geography of the Ludwig-Maximilians-Universität in Munich, Germany as part of the GLOWA-Danube project, which was funded by BMBF (Federal Ministry of Education and Research) from 2000 to 2010. The support is gratefully acknowledged. The authors want to thank the Editor Bart van den Hurk and the anonymous reviewers for their valuable remarks which considerably improved the paper.

### **8.7.     *Transition to Publication III***

The study of publication II has introduced the bi-directional coupling approach and demonstrated the resulting impacts upon the simulation results for the coupling domain of Central Europe. For quality statements about the results from the online coupling, comparisons to measured data and validation of the water balance for a specific catchment are carried out in publication III. Therefore, the Upper Danube catchment was chosen, since in the framework of the GLOWA-Danube project, the data from a dense network of meteorological monitoring stations and gauge measurements were available and the water balance of the Upper Danube was well researched.

Atmospheric responses to the online coupling and occurring feedbacks in the catchment are described. The results from online and offline simulations are compared to measurements. Thus, a validation of the bi-directional coupling approach was possible. It is shown that the investigated near surface air-temperature and the components of the water balance, precipitation, evapotranspiration and runoff are improved by the online coupling.

### **Abstract**

Most land surface hydrological models (LSHMs) take land surface processes (e.g. soil-plant-atmosphere interactions, lateral water flows, snow and ice) into detailed spatial account. On the other hand, they usually consider the atmosphere as exogenous driver only, thereby neglecting feedbacks between the land surface and the atmosphere. Regional climate models (RCMs), on the other hand, generally describe land surface processes much coarser but naturally include land-atmosphere interactions. What is the impact on RCMs performance of the differently applied model physics and spatial resolution of LSHMs? In order to investigate this question, this study analyses the impact of replacing the land surface model (LSM) within a RCM by a LSHM.

Therefore, a 2-way coupling approach was applied for a full integration of the LSHM PROMET ( $1 \times 1 \text{ km}^2$ ) and the atmospheric part of the RCM MM5 ( $45 \times 45 \text{ km}^2$ ). The scaling interface SCALMET is used for down- and upscaling the linear and non-linear fluxes between the model scales.

The response of the MM5 atmosphere to the replacement is investigated and validated for temperature and precipitation for a 4 year period from 1996 to 1999 for the Upper-Danube catchment. By substituting the NOAH-LSM with PROMET, simulated non-bias-corrected

near surface air temperature significantly improves for annual, monthly and daily courses, when compared to measurements from 277 meteorological weather stations within the Upper-Danube catchment. The mean annual bias was improved from -0.85 K to -0.13 K. In particular, the improved afternoon heating from May to September is caused by increased sensible heat flux and decreased latent heat flux as well as more incoming solar radiation in the fully coupled PROMET/MM5 in comparison to the NOAH/MM5 simulation. Triggered by the LSM replacement, precipitation overall is reduced, however simulated precipitation amounts are still of high uncertainty, both spatially and temporally. The distribution of precipitation follows the coarse topography representation in MM5, resulting in a spatial shift of maximum precipitation northwards the Alps. Consequently, simulation of river runoff inherits precipitation biases from MM5. However, by comparing the water balance, the bias of annual average runoff was improved from 21.2 % (NOAH/MM5) to 4.4 % (PROMET/MM5) when compared to measurements at the outlet gauge of the Upper-Danube watershed in Achleiten.

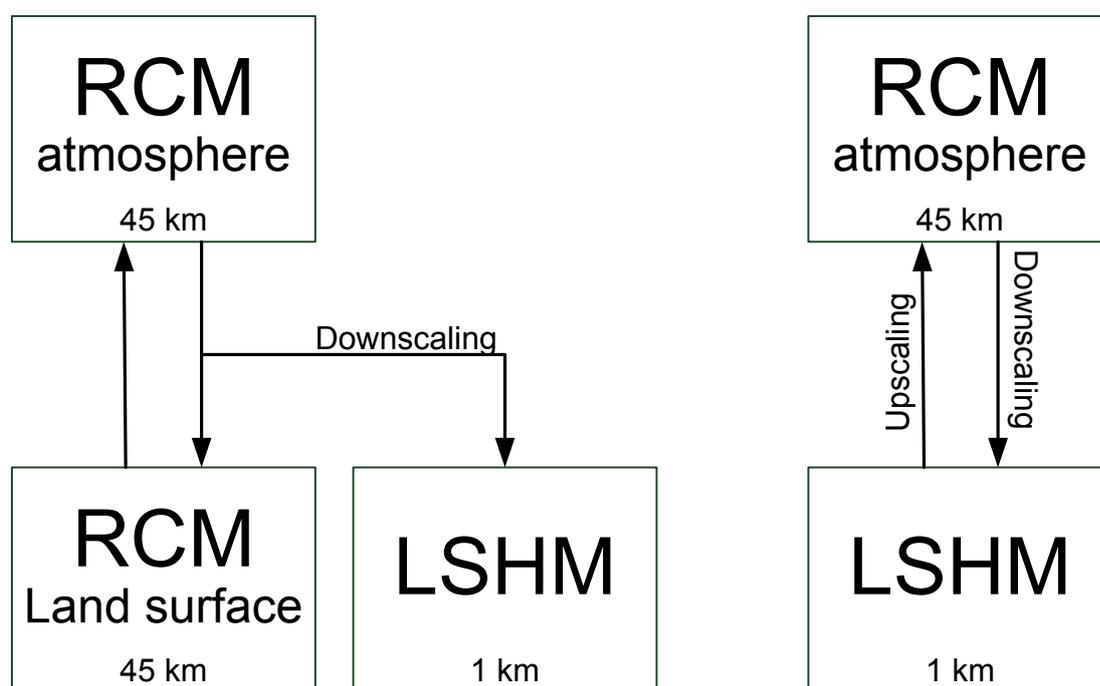

## Introduction

Land surface models designed for hydrological studies (LSHMs) need meteorological data as input in order to simulate the pathway of water and energy at the land surface. This can be provided by measurements or regional climate models (RCMs). The latter is often used for hydrological impact studies on climate change scenarios. However, most LSHMs consider the atmosphere as an exogenous model driver only, applying a 1-way coupling approach and usually a correction of the systematic biases of temperature and precipitation (Marke et al., 2011a; Senatore et al., 2011), when driving LSHMs with data provided by a RCM (see Figure 8.8.1). Thereby, the 1-way coupled model chain includes redundancy of two different land surface models, describing the same land surface processes. By not allowing for feedbacks between the downstream LSHM and the atmosphere of the RCM, inconsistencies occur when driving the LSHM offline with RCM output (Zabel et al., 2012).

Physically based LSHMs are usually designed to simulate small scale river basins on high spatial resolution, which allows for modelling physical processes with high process and spatial detail. They have intensely been validated reproducing gauge measurements and have recently extended from small to large scale river basins in the order of 1 million km<sup>2</sup> (Mauser and Bach, 2009; Ludwig et al., 2003). However, they go beyond reproducing runoff at gauges of small scale catchment areas and now consider in detail land surface processes (Garcia-Quijano and Barros, 2005; Kuchment et al., 2006; Kunstmann et al., 2008; Ludwig and Mauser, 2000; Mauser and Bach, 2009; Schulla and Jasper, 1999). The physically based models aim at understanding the interactions between the different land surface compartments, namely soil, vegetation, snow and ice in producing the resulting river runoff. Some are not calibrated with measured runoff and, thereby, in a strict sense, they conserve mass and energy at the land surface. They include detailed descriptions of vertical and lateral soil water and energy flows, vegetation dynamics and related flow regulations, snow and ice dynamics as well as energy and mass exchange with the atmosphere and, accordingly, land surface processes in the soil-plant-atmosphere continuum. However, for modelling runoff over mountainous terrain with RCM forcing adequately, a bias correction of the RCM data is necessary (Marke et al., 2011b).

On the other hand, LSMs designed for the use within RCMs, developed from coarse spatial resolution on continental scales, use a comparatively simple physical description of the land surface processes with simple parameterizations, in order to keep computational demand low

(Chen and Dudhia, 2001; Henderson-Sellers et al., 1995; Henderson-Sellers et al., 1996; Pitman, 2003; Pitman and Henderson-Sellers, 1998; Wood et al., 1998). During the past years, they have become more and more complex, considering vegetation dynamics, biogeochemical processes, surface and subsurface hydrology, dynamic development of snowpack and include representations of urban and artificial areas as well as lakes (van den Hurk et al., 2011). Due to the latest developments, LSM and LSHMs overall seem to converge in terms of their physical skills. Nevertheless, a gap remains between the spatial resolution of RCMs and LSHMs. Therefore, we investigate the impacts of directly coupling a high resolution LSHM with a low resolution RCM using an appropriate up-and downscaling approach.

**Figure 8.8.1: Schematic illustration of 1-way (left) and 2-way coupling (right) a LSHM with a RCM.**

As shown in multiple studies, an improvement of physical parameterization and spatial resolution in RCMs is supposed to improve simulation results (Hagemann et al., 2001; Zängl, 2007a). 2-way coupling a LSHM with a RCM potentially seems to be a very powerful approach (Chen and Dudhia, 2001). Mölders and Raabe (1997) e.g. applied a 2-way coupling approach for a 24 h weather prediction forecast for a small domain of  $225 \times 150 \text{ km}^2$ . Simulating large scale watersheds and longer time periods could not be considered at that time due to computational limitations. The central question concerning this study is, whether RCMs could benefit in terms of an improved modelling of atmospheric and land surface processes (e.g. temperature, precipitation, evapotranspiration, and runoff) from the spatially

and process-wise more detailed land surface description when substituting the LSM of the RCM with a high spatial resolution LSHM and a spatial scaling mechanism.

In this study we take the Upper-Danube catchment ( $A = 77000 \text{ km}^2$ ) over a 4-year period from 1996 - 1999 to compare simulation results of atmospheric and land surface hydrology variables and simulated water balance with measurements, using the original MM5-NOAH and a replacement of NOAH with the high resolution PROMET-LSHM and a bi-directional scaling interface.

## Materials and Method

The RCM applied in this study is the fifth-generation Mesoscale Model (MM5) (Grell et al., 1994), developed by the Pennsylvania State University (Penn State) and the National Center for Atmospheric Research (NCAR). It was modified and adapted to our specific simulation requirements and our specific model domain (Pfeiffer and Zängl, 2009; Zängl, 2002). MM5 is used in climate mode with a horizontal spatial resolution of 45 km and an internal time step of 135 seconds. ECMWF ERA-40 reanalysis-data (Uppala et al., 2005) are used to nudge the double-nested MM5 model solutions 6-hourly at the lateral boundaries of the first nesting domain that covers the European continent with 79 grid-boxes in west-east and 69 grid-boxes in south-north directions (Pfeiffer and Zängl, 2009).

The NOAH-LSM (Chen and Dudhia, 2001) as an integral component of MM5 is an advanced physically based LSM designed for the use in atmosphere application such as MM5 and, thus, it uses the same spatial resolution than the atmosphere model. It has been developed with the goal of a simple but robust parameterization, taking the most important aspects of land surface hydrology into account (Chen and Dudhia, 2001). As a physically based LSHM, PROMET uses a more hydrological view on the land surface with a more detailed spatial resolution of 1 km and different physical formulations than the NOAH-LSM (Zabel et al., 2012). Detailed model descriptions of PROMET can be found in (Mauser and Bach, 2009, Muerth and Mauser, 2012).

An enhanced 2-way coupling approach, which takes care of the different spatial resolutions of the two components is used in this study for fully coupling the LSHM PROMET with the RCM MM5 for the model domain of Central Europe (Zabel et al., 2012). Therefore, the NOAH-LSM is replaced with PROMET and the bi-directional scaling tool SCALMET (Zabel et al., 2012). Thus, PROMET results of scalar surface fluxes, which are latent and sensible heat, short- and longwave outgoing radiation and momentum, are linearly upscaled to 45 km. These upscaled fluxes serve as the lower boundary conditions for the MM5 atmosphere and, consequently, MM5 results downscaled to 1 km provide the inputs to PROMET (Zabel et al., 2012). Besides, the non-scalar radiation temperature at the surface or at the top of the vegetation canopy respectively is given to MM5, since it is needed for initializing the convection scheme at each coupling time step. It is calculated from the upscaled emissivity and the upscaled emission of longwave radiation of the PROMET land surface using the Stefan-Boltzmann-law. The adjustable coupling time step for exchanging the fluxes between

both models in both directions was set to 9 min in the current study. This allows PROMET to run synchronously with MM5, which uses an internal time-step of 135 s.

SCALMET assures the conservation of mass and energy during the up- and downscaling process. In order to guarantee for a consistent coupling between the models, a bias correction is not applied in this study. Further, PROMET maintains mass and energy at the land surface and is not calibrated with measured discharges.

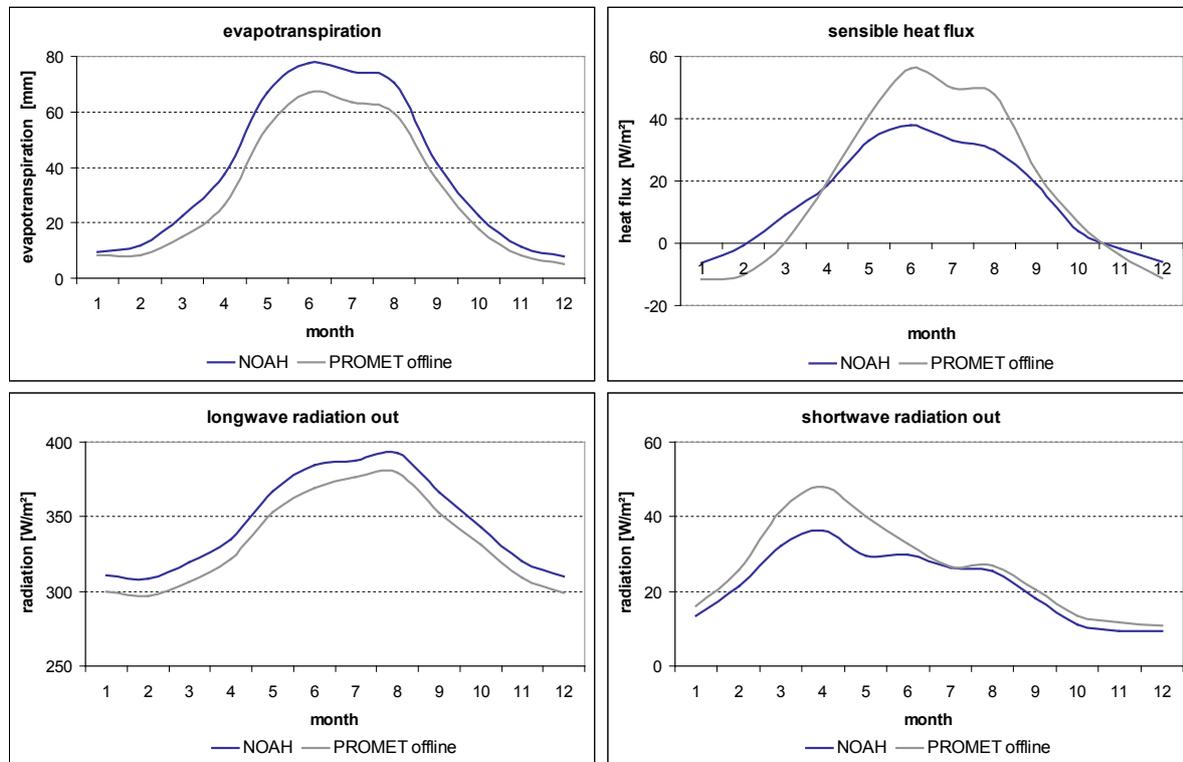

A more detailed model comparison between PROMET and NOAH and methodological explanation of the coupling approach between PROMET and MM5 is given in Zabel et al. (2012). Within this paper, the results of three different configurations are compared with measurements (see Figure 8.8.1):

- NOAH fully, interactively coupled with the atmospheric part of MM5
- PROMET offline driven with MM5 output
- PROMET interactively (bi-directionally) coupled with MM5, applying the 2-way coupling approach

All simulation results are compared with measurements from 277 meteorological weather stations, spatially interpolated to the Upper Danube catchment. The catchment is situated in Central Europe, has an area of 76.653 km<sup>2</sup> and is characterized by a complex terrain, covering parts of the Alps in Southern Germany, Austria, Switzerland and Italy. Altitudes reach from 4049 m a.s.l. at Piz Bernina to 287 m a.s.l. at the catchment's outlet at the gauge in Achleiten. The lowlands north of the Alps are characterized by heterogeneous land and soil patterns, intense agriculture and high population density. The prevailing climate is characterized by the temperate latitudes with an annual precipitation gradient ranging from 550 mm in the Northern part of the catchment to more than 2000 mm in the Alps.

## Results and Discussion

### Differences between PROMET and NOAH

**Figure 8.8.2: Spatially averaged monthly land surface mass and energy fluxes (evapotranspiration, sensible heat flux, long-wave outgoing radiation, short-wave outgoing radiation) for the Upper-Danube catchment simulated with the NOAH-LSM and with PROMET offline respectively for the years 1996-1999.**

As can be seen in Figure 8.8.2, offline driven with RCM output, PROMET simulates less long-wave outgoing radiation and more short-wave outgoing radiation than NOAH. The lower long-wave outgoing radiation is mainly due to lower values of land surface emissivity within the PROMET parameterization than within the NOAH parameterization, while the higher amount of reflected short-wave radiation mainly results from a more heterogeneous land use and land cover in PROMET, having a higher number of land use/cover classes with high albedo values, such as urban area or rock. Further, snow cover increased short-wave reflection especially from March to May due to a spatially more detailed underlying topography, resulting in higher elevations in the Alpine area. In the PROMET simulation, snow cover still was predominant in the higher altitudes in May, while the high altitudes are averaged out in the NOAH topography due to the coarse spatial resolution.

Overall, net radiation for the Upper-Danube catchment is higher by 8 W/m<sup>2</sup>. This net radiation is further differently distributed into latent and sensible heat due to different assumptions in

the model's underlying land surfaces in terms of topography, soil and land use/cover properties (Zabel et al., 2012). Further, evapotranspiration is considerably lower due to impervious surfaces, such as urban area and rock that do not contribute to transpiration in PROMET while NOAH mainly implements a mixture of cropland and forest (Zabel et al., 2012) for the Upper-Danube. Consequently, sensible heat is higher in summer but lower in the winter months (Figure 8.8.2) due to snow cover effects in the PROMET simulation in the Alpine area. While energy goes into snow melt instead of into sensible heat in the PROMET simulation, available net radiation has to become sensible heat in the NOAH-LSM. The higher spatial resolution in PROMET results in a more detailed modelling of the snow cover, especially in the spatially heterogeneous Alps with strong impact on the sensible heat flux. Thus, more energy goes into snow melt in the PROMET simulation, which explains the overall lower heat fluxes in the PROMET simulation although net radiation is a little higher.

### **Atmosphere responses**

By replacing NOAH with PROMET and a bi-directional scaling interface, a full interactive coupling with the atmospheric part of MM5 is achieved and the modelled atmosphere responds to the replacement of the LSM.

### ***Planetary boundary layer***

Due to the tendency of higher sensible heat flux without snow cover in the PROMET model, the height of the planetary boundary layer is increasing in the PROMET/MM5 bi-directional coupling in summer and decreasing in winter over the Upper-Danube catchment (Figure 8.8.3). Consequently, this has far-reaching implications to the moisture content of air masses as well as the stability of stratification. Sensible heat is a sensitive parameter, affecting cloud fraction, convection and, thus, precipitation as well as solar radiation. In our setup, MM5 uses the Kain-Fritsch-2-scheme which turned out to be the best parameterization of the convection scheme for the simulation area, being tested with the NOAH-LSM with respect to simulated rainfall amounts (Pfeiffer and Zängl, 2010). This scheme was further applied to the PROMET/MM5 simulation, without adaptation and without testing other convection parameterization schemes in combination with PROMET.

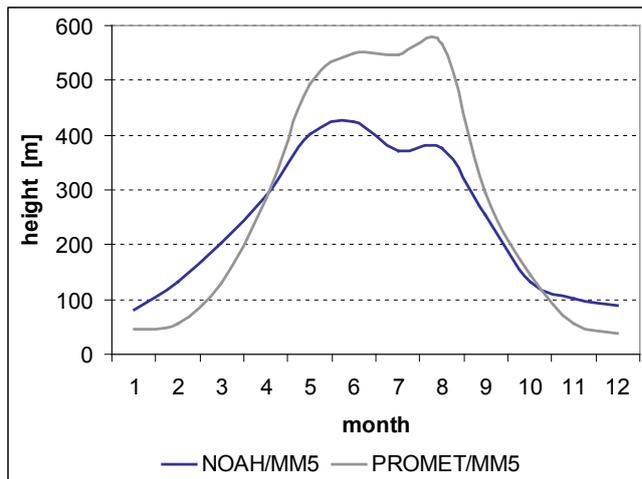

Figure 8.8.3: Monthly course of the planetary boundary layer height (1996-1999).

### Solar incoming radiation

Total incoming radiation, as the sum of direct and diffuse radiation, increases by the use of the PROMET land surface from 106 W/m<sup>2</sup> (NOAH) to 112 W/m<sup>2</sup>. Measurements of radiation (117 W/m<sup>2</sup>) calculated via the proportion of cloud cover from 277 meteorological stations are compared to simulation results in Figure 8.8.4. The monthly incoming short-wave radiation is increased in the summer months and, thereby, closer to the measurements while the influence of the land surface on the atmospheric conditions is low in winter. The basic shape of the PROMET and NOAH curves is similar since it is mainly controlled by the passing low-pressure systems imposed onto the simulations by the ERA-40 lateral boundary forcing.

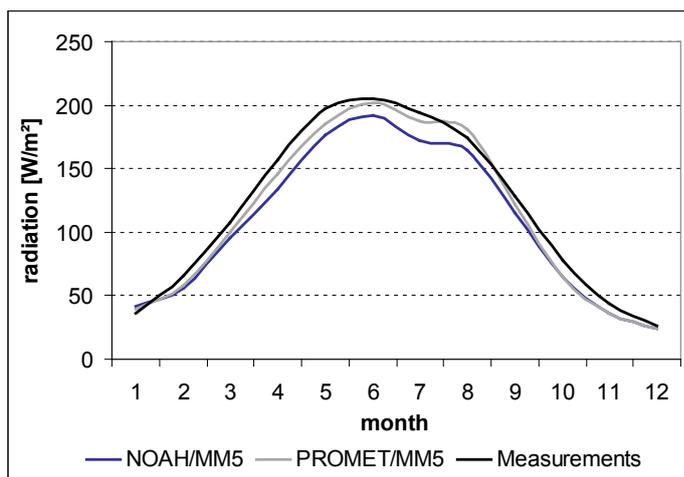

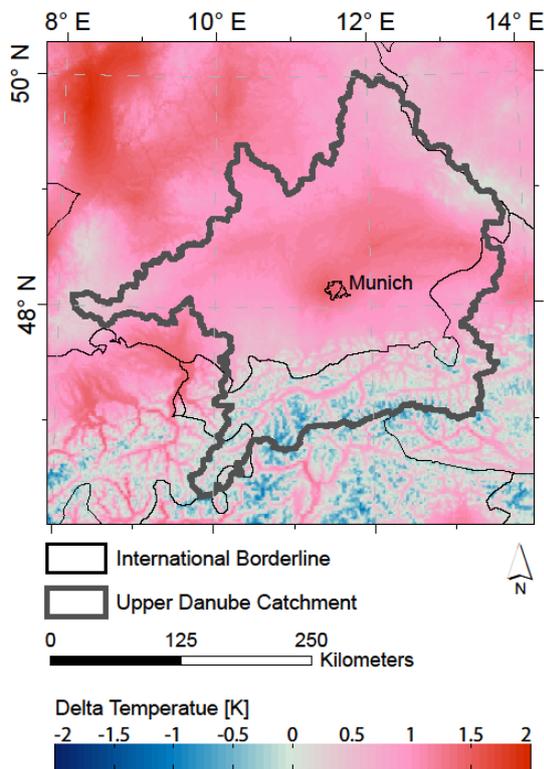

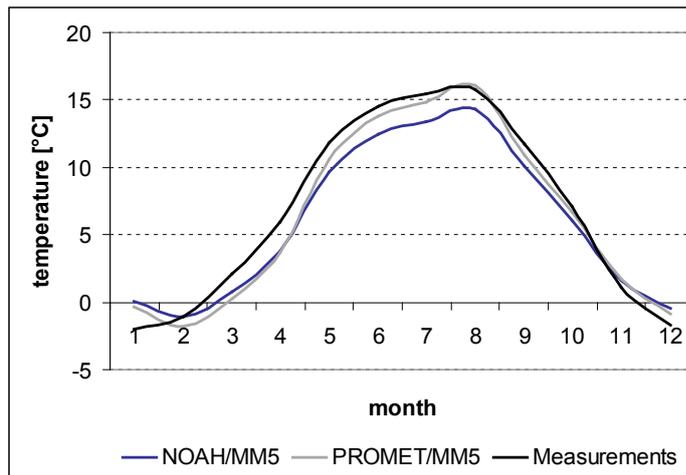

Figure 8.8.4: Monthly course of the total incoming short-wave radiation (1996-1999).

## Temperature

**Figure 8.8.5: Difference plot between PROMET/MM5 and NOAH/MM5 annual mean near surface air temperature in the Upper Danube Basin, downscaled to 1 km.**

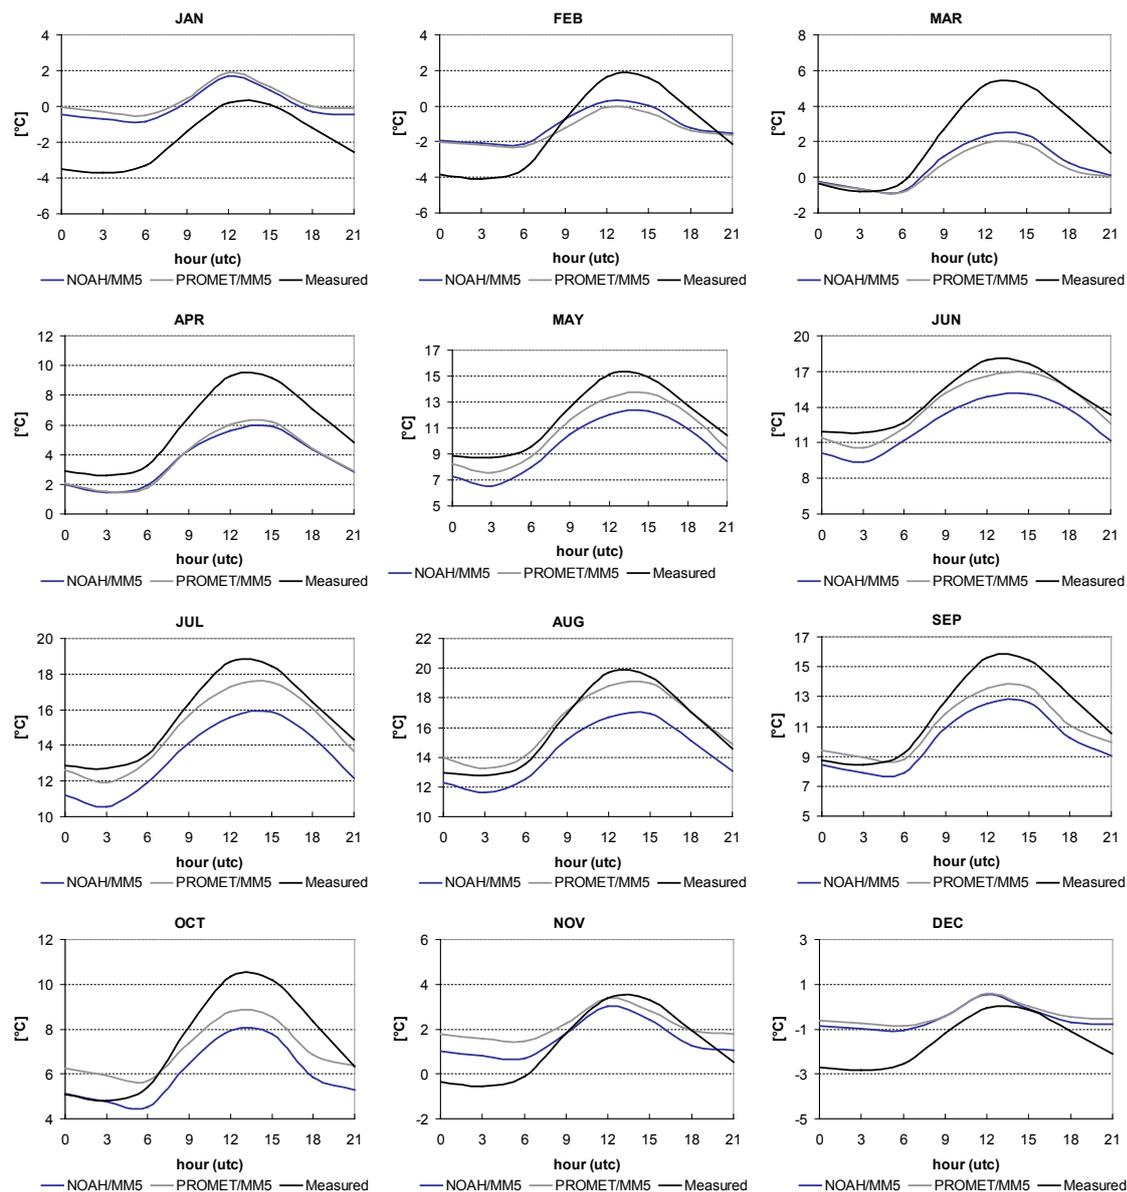

The higher solar incoming radiation as well as lower evaporative cooling in PROMET results in an increase of the annual mean near surface air temperature from  $5.93^{\circ}\text{C}$  to  $6.65^{\circ}\text{C}$  in the fully coupled PROMET/MM5 simulations. The increase mainly occurs North of the Alps and near the city of Munich (Figure 8.8.5). Measurements from 277 meteorological weather stations show  $6.78^{\circ}\text{C}$  for the Upper-Danube catchment and the respective years. Thus, annual bias could be reduced from  $-0.85\text{ K}$  to  $-0.13\text{ K}$ . In addition, the monthly behaviour was improved in fully coupled PROMET/MM5 simulations when compared to measurements (see Figure 8.8.6).

**Figure 8.8.6: Monthly mean temperature of fully coupled NOAH-MM5 simulation, PROMET-MM5 simulation in comparison with measurements in the Upper-Danube catchment.**

Figure 8.8.7 shows the simulated diurnal cycle of the near surface air temperature for NOAH/MM5, PROMET/MM5 and measurements respectively. The impact of the land surface is marginal in the winter months due to low energy inputs on the land surface. Therefore, the bi-directional coupling approach with PROMET has almost no effect on the air temperature in the winter months. On the contrary, the diurnal cycle is strongly affected by the changed land surface in the summer months. Here, by using PROMET, near surface air temperature heats up faster and stronger. A cold bias of up to 2 K in the NOAH/MM5 simulation, especially in the afternoon hours in summer, corresponds to the results of Pfeiffer and Zängl (2009). Compared to measurements, a clear improvement can be investigated from May to September, where the diurnal course and particularly the maximum can be reproduced considerably better.

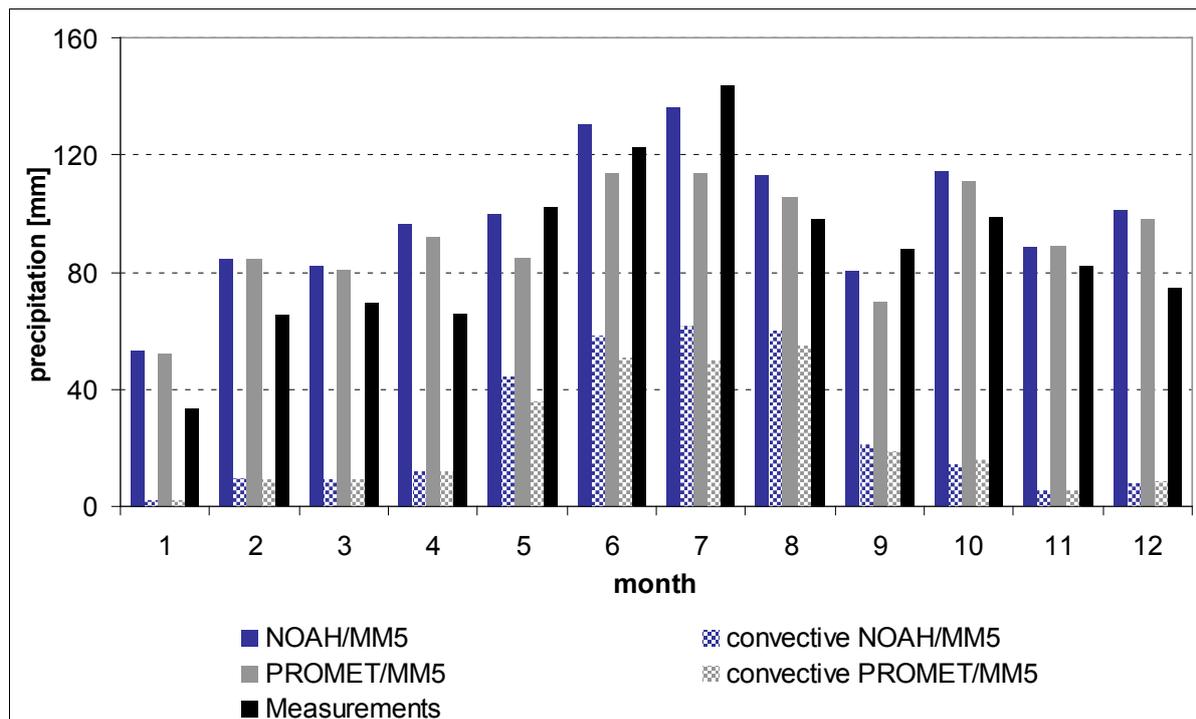

In August e.g., the mean maximum temperature is measured at 19.7° C. While the NOAH/MM5 simulations only reaches 16.9° C in the afternoon hours, the changed lower boundary conditions lead to a mean maximum daily temperature of 19.0° C in bi-directionally coupled PROMET-MM5 simulations.

**Figure 8.8.7: Monthly mean diurnal cycle (1996-1999) of the near surface air temperature (3-hourly) for the Upper-Danube catchment.**

### **Precipitation**

The measured annual precipitation for the area of the Upper-Danube is 1045 mm. While the NOAH/MM5 approach calculated 1180 mm, the fully coupled PROMET/MM5 approach simulated 1095 mm. Thus, annual bias was reduced from 12.9 % to 4.8 %. In particular, winter and spring precipitation is clearly overestimated (Figure 8.8.8) in both MM5 simulations. However, precipitation amounts are reduced in the summer months as a respond of coupling the PROMET land surface with MM5, while winter and spring precipitation hardly changes (Figure 8.8.8).

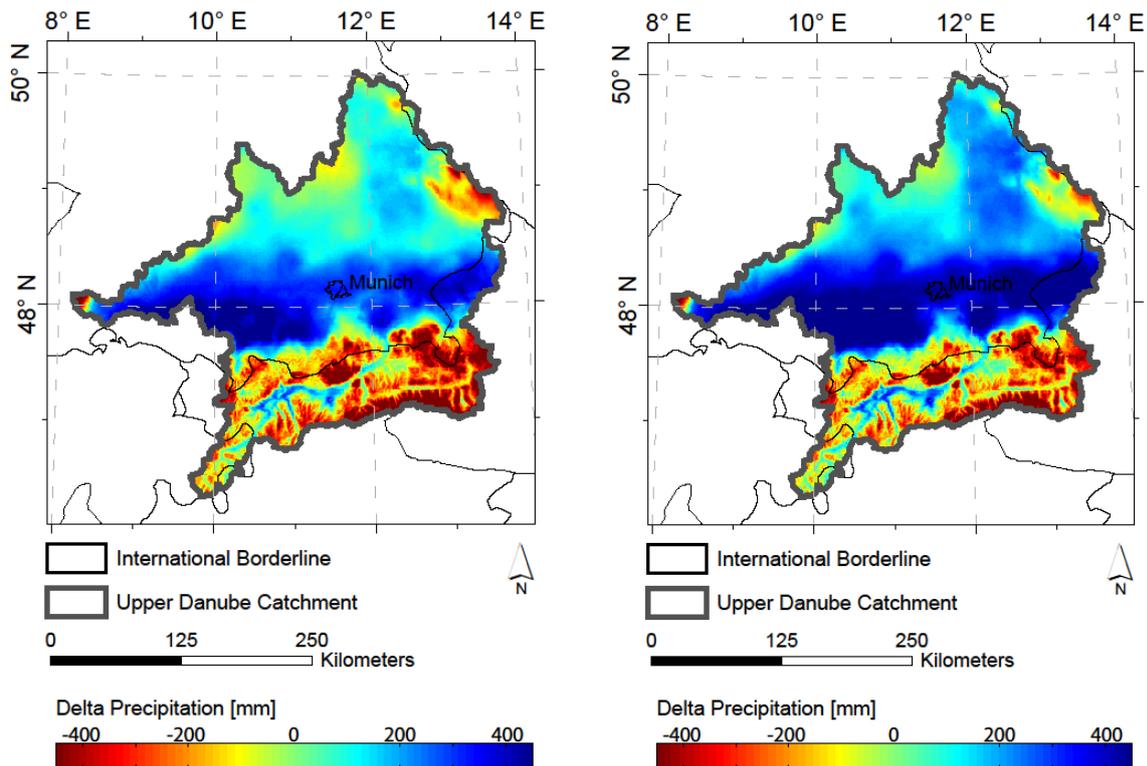

**Figure 8.8.8: Monthly convective and total precipitation of MM5 simulations coupled with NOAH and PROMET compared to measurements.**

The decrease of monthly precipitation from May to September in the results of PROMET/MM5 is mainly due to the decrease of convective precipitation by 20 %, while non-convective precipitation is reduced by 9 % (Figure 8.8.8). Therefore, it can be pointed out that the change of the land surface predominantly affects convective precipitation that finally decreases during summer for the Upper-Danube catchment. This results in an improvement for June and August but not in May and July.

However, heavy precipitation events such as in May 1999 due to special weather conditions are not properly reproduced in the Upper-Danube in both simulations where heavy precipitation is generally underestimated (Zängl, 2007b).

Further, Zängl (2007a) found a resolution-dependence, drastically affecting the MM5 model skill in the Alpine part of the model domain. By refining the mesh size from 9 km to 1 km, simulated precipitation could be considerably improved, due to a better representation of the topography in the atmosphere model. However, the coarse resolution of MM5 in our study (45 km) is not suitable for reproducing precipitation properly in the Alps and the foothills of the Alps. The coarse resolution of the MM5 topography results in a northwards shift of precipitation away from the Alps, when compared with measurements. Consequently, precipitation is overestimated in the Alpine foreland and underestimated in the Alps, due to leeward effects (see Figure 8.8.9).

**Figure 8.8.9: Over- and underestimation of annual simulated PROMET/MM5 (left) and NOAH/MM5 (right) precipitation in the Upper Danube Basin, downscaled to 1 km and subtracted from measurements.**

The use of PROMET instead of NOAH does not change the coarse resolution of the MM5 underlying topography. Therefore, the precipitation shift appears in both simulations while the annual overestimation in the alpine foreland is reduced in the PROMET simulations while at the same time the underestimation in the Alpine regions is increased. From this, we conclude that precipitation improved in the Northern part of the Upper-Danube catchment with low influence of the Alps and low relief.

Advective inflowing air masses passing the MM5 model domain, dominantly driven by the lateral boundary conditions (ERA-40), are one source of uncertainty, which ERA-40 data inherit to the RCM.

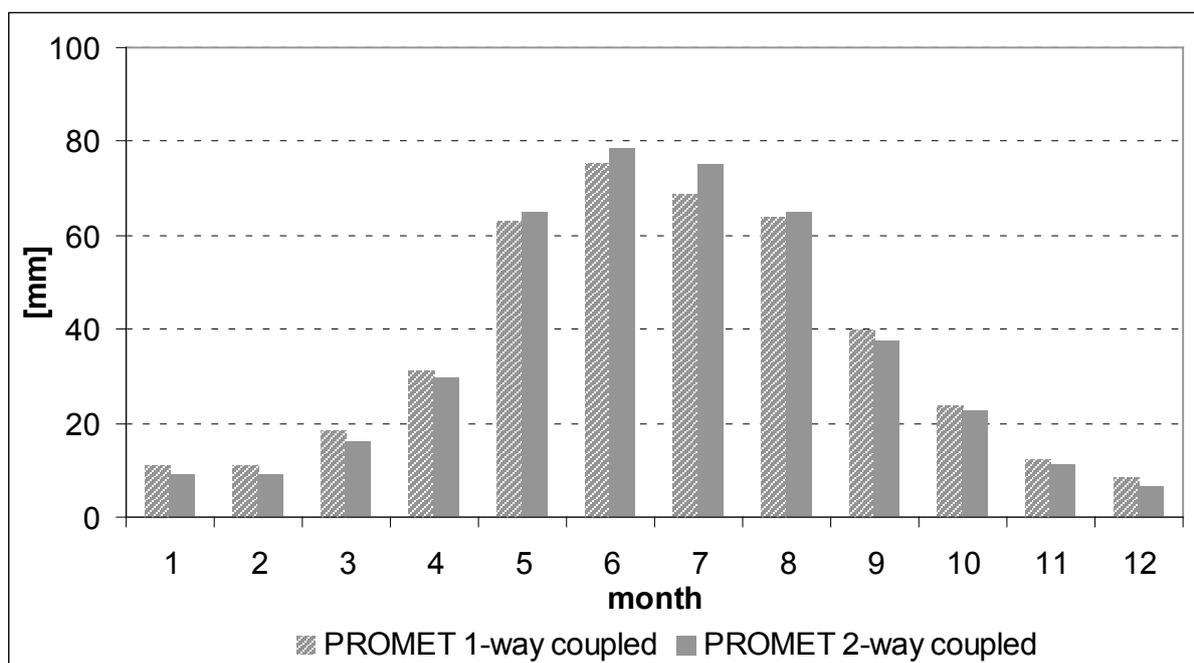

The coarse resolution of MM5 is another source for overestimating precipitation especially in winter, which coincides with the findings of Pfeiffer and Zängl (2010).

In addition, a systematic underestimation of wintertime snowfall in the observational dataset mainly in the Alpine domain should be considered in the evaluation.

## Feedback effects

### *Evapotranspiration*

By coupling PROMET bi-directionally with MM5, simulated evapotranspiration increases between May and August and decreases slightly from September to April due to changed atmospheric conditions such as the increased temperature and solar radiation that feed back to the land surface in the bi-directional coupling case (Figure 8.8.10).

**Figure 8.8.10: Monthly mean evapotranspiration in the Upper Danube Basin of 1-way and 2-way coupled PROMET simulations (1996-1999).**

Zabel et al. (2012) showed that the change of evapotranspiration in the fully coupled PROMET/MM5 simulations highly depends on the simulated soil moisture. Since wilting point is hardly ever reached in the Upper-Danube catchment, evapotranspiration is marginally affected by soil moisture and can thereby increase in summer.

### *Water Balance*

By the use of PROMET's baseflow, interflow and surface runoff as well as channel hydraulics components, simulated time series of monthly, daily and hourly runoff can be compared against hourly gauge measurements (Mauser and Bach, 2009). NOAH has the ability for modelling surface runoff formation but lacks in the option for simulating of lateral and river channel flow.

However, it is not the intention of this study to estimate the ability of bias corrected RCM inputs to reproduce runoff in the Upper Danube watershed. Since a bias correction would have been counterproductive in this study, biases of the RCM, particularly precipitation biases are handed over to the land surface components and, therefore, drastically affect runoff simulations.

Due to the coarse spatial resolution of 45 km in our study, the spatial patterns of precipitation follow the coarse spatial resolution of the underlying MM5 topography ( $45 \times 45 \text{ km}^2$ ). The scale mismatch to the 1 km topography of PROMET, therefore, leads to inadequate spatial shifts and biases in runoff that cannot be corrected without a bias correction.

Consequently, analogously to precipitation, a spatially detailed analysis of simulated river runoff underlies strong uncertainties in the Alps and the Alpine foreland. Nevertheless, regarding the annual water balance, simulated and annual averaged river runoff at the catchment's outlet was compared to the measured annual average runoff at the outlet of the Upper Danube Basin in Achleiten, which was determined to be  $1412 \text{ m}^3 \text{ s}^{-1}$  for the considered years. The results are shown in Table 8.8.1.

Mean surface runoff [mm] simulated by the NOAH-LSM for the Upper-Danube catchment and converted into the catchment's discharge, is  $1712 \text{ m}^3 \text{ s}^{-1}$ . Thus, NOAH/MM5 strongly overestimates annual mean runoff. One way coupling of PROMET with MM5 results in a simulated average lateral river runoff of  $1583 \text{ m}^3 \text{ s}^{-1}$  and a considerable improvement from the NOAH/MM5 case. The full 2-way coupling of PROMET and MM5 leads to a simulated average river runoff of  $1474 \text{ m}^3 \text{ s}^{-1}$ . This value can be considered to compare quite well with the observed  $1412 \text{ m}^3 \text{ s}^{-1}$ . Thus, the annual bias could be reduced from 21.1 % (NOAH) to 4.4 % (2-way coupled PROMET).

**Table 8.8.1: Measured annual mean runoff at the outlet of the Upper Danube catchment at Achleiten in comparison with simulated runoff of NOAH/MM5 and PROMET/MM5 in either 1-way or 2-way coupled configuration.**

Model Configuration	Runoff
NOAH	$1712 \text{ m}^3 \text{ s}^{-1}$
PROMET, 1-way coupled	$1583 \text{ m}^3 \text{ s}^{-1}$
PROMET, 2-way coupled	$1474 \text{ m}^3 \text{ s}^{-1}$
Measurements	$1412 \text{ m}^3 \text{ s}^{-1}$

## Conclusions

In this study, we investigated the impacts of replacing the land surface module of the RCM MM5 with the LSHM PROMET for the Upper-Danube catchment. As shown, it is possible to use LSHMs embedded in RCMs, which offers new opportunities for both, the atmospheric and the hydrological community.

Through that replacement, the spatial resolution of the land surface representation improved from 45 km<sup>2</sup> to 1 km<sup>2</sup>, which was dealt with by a bi-directional scaling interface that arranged the 2-way coupling between the models. It could be shown that different spatial scales and assumptions between the land surface models NOAH and PROMET lead to different simulation results of latent and sensible heat, as well as long- and short-wave outgoing radiation. Thereby, PROMET evapotranspiration was lower, while sensible heat flux tends to be higher. By applying the full 2-way coupling between PROMET and MM5, the atmosphere responded to the changed lower boundary conditions. As a consequence, mean annual temperature increased from 5.93° C to 6.65° C due to more incoming solar radiation and less evaporative cooling which lead to more sensible heat flux. Compared to meteorological measurements (6.78° C), simulated near surface air temperature improved also for monthly and diurnal courses. Particularly afternoon heating was modelled more adequately by the use of PROMET. The impact of the PROMET land surface scheme on changes in the atmosphere is strongest in summer, when energy transformation at the land surface strongly affects atmosphere processes.

The impact on precipitation is difficult to diagnose, due to high uncertainties induced by the complex terrain of the catchment. Overall, precipitation was reduced mainly due to decreased convective precipitation in summer which can be explained by the rise of the planetary boundary layer due to more sensible heat flux. As a result, the moisture content of air masses is reduced and cloud fraction and convection are finally impeded. However, simulated precipitation shows a spatial shift northwards into the Alpine forelands when compared to measurements in the Upper-Danube catchment, as a result of the coarse description of the topography in MM5. The high temporal and spatial bias of precipitation, mainly in the Alps and the Alpine foreland is inherited to runoff simulation results in PROMET.

The NOAH river runoff for the Upper-Danube catchment converted from surface runoff [mm] was 1712 m<sup>3</sup> s<sup>-1</sup>, which means a strong overestimation of annual runoff. Simulated annual

river runoff improved to  $1583 \text{ m}^3 \text{ s}^{-1}$  when using the 1-way coupled PROMET/MM5 approach due to less precipitation and higher evapotranspiration. Finally, the fully coupled PROMET/MM5 approach improved the simulation of the outlet gauge in Achleiten to  $1474 \text{ m}^3 \text{ s}^{-1}$  without a bias correction in comparison to gauge measurements in Achleiten ( $1412 \text{ m}^3 \text{ s}^{-1}$ ).

We conclude from these results that when comparing simulation results of an RCM using different land use schemes, all investigated meteorological and hydrological parameters improved in comparison with observations when moving from NOAH/MM5 to a fully-coupled PROMET/MM5.

## 9. SYNTHESIS

The aim of the thesis was the bi-directional coupling of the LSHM PROMET with the RCM MM5. The complexity of interactions, responses and feedbacks which occur between the atmosphere and the heterogeneous land surface were the key issues addressed in the publications.

It can be pointed out that the land surface does remarkably affect land surface matter and energy fluxes. It was proven that a more detailed view on land surface heterogeneity is evidentially important to describe hydrological processes at the land surface. Atmospheric responses were largely sensitive to land surface heterogeneity, due to effects on albedo, mass and heat fluxes that result from different land surface land cover, soil and topographic properties. Thereby, the prevailing hydrological conditions determined both the positive or negative sign and the strength of the feedbacks.

An approach was presented, that enables a bi-directionally coupling between LSHMs and RCMs across different spatial scales. Thereby, PROMET is able to provide lower boundary conditions for RCMs. In comparison to the NOAH-LSM that is used within the RCM MM5, PROMET more realistically matches land surface heterogeneity. The physical formulations are taking hydrological aspects at the land surface, such as soil and plant processes, runoff formation, snowpack and evapotranspiration, more detailed into account. Consequently, land surface fluxes of heat and matter differ between PROMET and NOAH both, spatially and temporally. The processes in the atmosphere respond adequately and in a comprehensible way to the replacement of the NOAH-LSM with PROMET. As shown, the air temperature, the planetary boundary layer height, cloud fraction and precipitation are influenced by the PROMET land surface. The changed atmospheric conditions feed back to the land surface. Consequently, positive and negative feedbacks lead to increased and decreased evapotranspiration, depending on the prevailing hydrological conditions, varying both spatially and temporally.

By the use of PROMET, all investigated processes were improved for seasonal, monthly and diurnal cycles in comparison with measurements for the Upper Danube catchment. Precipitation was at least improved for annual values, however still high uncertainties remain. The improved representation of the land surface has led to better simulation of the diurnal

variation of surface heat and water fluxes, improving the water balance and hence the forcings for boundary-layer dynamics and convection.

In conclusion, the results can be viewed from both, the meteorological and the hydrological point of view. From the meteorological point of view, the bi-directional coupling between the LSHM PROMET and the RCM MM5 resulted in a more realistic simulation of the lower boundary conditions that yielded in improved simulation of atmospheric processes. Thus, it was demonstrated that bi-directional coupling LSHMs with RCMs can make valuable contributions to an improved land surface representation in current RCMs.

From the hydrological point of view, the study addresses the topic of the inconsistency between atmospheric and land surface models. It shows that due to more detailed parameterizations, formulations and underlying land surface information, the equilibrium hydrological balance in the PROMET model is different from the NOAH model, but moreover, that this difference is regionally amplified when the PROMET model is allowed an online interaction with the atmosphere.

## 10. OUTLOOK

Due to the successful application of the bi-directional coupling approach, exemplarily for a 4-year simulation period, an extension to long term scenarios, e.g. until 2100, would be a possible next step in further studies. This could further improve the understanding and knowledge about future climate and land-surface hydrological feedbacks, such as permafrost melting effects on climate. Thus, a contribution could be given to improve climate scenarios.

For further improvements, the bi-directional hydrological coupling should not only be applied to RCMs, but also to GCMs. This could be achieved by allowing the RCM to dynamically exchange fluxes with the model providing the lateral boundaries, or by coupling the PROMET high resolution land surface with a GCM bi-directionally. However, global simulations at a 1 km spatial grid at the land surface would require a massive increase of computational resources.

A potentially powerful approach for improving the interrelationship between the land surface and the atmosphere processes would be the extension of the land surface model grid from the boundary into the lower atmosphere layers. This would particularly improve the simulation of small-scale clouds, which would aid in improving precipitation patterns and amounts in high relief areas (Pitman, 2003; Zängl 2007).

Another step forward would be the inclusion of the nitrogen and carbon cycle in the land-atmosphere exchange, which is already implemented in the scaling tool SCALMET. So-called 'third generation' LSMs (Pitman, 2003; Kabat et al., 2004) take advantage of the relationship of photosynthesis and stomatal conductance (Farquhar et al., 1980), therefore including plants' carbon assimilation and uptake explicitly in the simulations. PROMET already provides the option that allows for the simulations of plants' carbon uptake (Hank, 2008). The integration of the carbon cycle in the bi-directional coupling approach would therefore be another obvious step that would contribute to further improvements in the land-atmosphere interrelations.

It became clear that the land surface and its hydrological characteristics are one of the key aspects of climate sensibility with respect to their influence on the climate through direct and indirect effects on climate variables. The human impacts upon the land surface, land use change, water management, urbanization and vegetation as well as impacts of climate change on the land surface, plants and the water cycle therefore are key issues concerning the land

surface that, however, must be considered more precisely in climate scenarios. This requires land surface hydrological models that are able to capture large spatial domains with high spatial resolution. A coupling with models from other scientific disciplines, such as economic models for detecting land use change and investigating ecosystem services, could be a promising future extension of coupling integrative processes.

## 12. APPENDIX

## 12.1. Underlying Model Formulations

This Section gives an overview of the underlying model formulations, used in the models NOAH and PROMET for describing the land surface evapotranspiration.

The LSMs applied in this study are the NOAH-LSM and PROMET. Both models describe the pathways of water and energy at the land surface in a physically based manner. Evapotranspiration is the sum of plant transpiration ( $E_t$ ) via soil, root, leaf and the stomata and evaporation from the bare soil ( $E_{dir}$ ) and evaporation of water intercepted by the canopy or other surfaces ( $E_i$ ) (Eq. A1). It is driven by the gradient of vapour pressure between the surface and the surrounding air, passing the laminar boundary layer into the free atmosphere, finally carried away by the turbulent mass transport of wind within the atmospheric boundary layer expressed by the aerodynamic resistance. Thus, modelling evapotranspiration is a complex issue which requires taking multiple aspects into account.

$$E = E_{dir} + E_i + E_t \quad (A1)$$

### 12.1.1. NOAH

The NOAH-LSM was originally designed for the use in RCMs and is part of the MM5 modelling system. The NOAH-LSM is an updated version of the OSU-LSM. A complete description of the NOAH and OSU-LSM is given in Chen and Dudhia (2001b, a) and Mitchell (2005). The older version of MM5 documented in Grell et al. (1994), already included a simple land surface model which does not take basic hydrological effects like snow cover into account. The land use had a coarse resolution and soil moisture was defined as a function of land use with seasonal values that cannot change during the simulation or respond to precipitation. Vegetation evapotranspiration and runoff processes were not included (Chen and Dudhia, 2001b).

The goal of the development of the NOAH-LSM was to implement an appropriate LSM for weather prediction and more hydrological applications that reflect the major effects of vegetation on the long-term evolution of surface evaporation and soil moisture and to get along with relatively few parameters for short and long-time within continental-domain applications. The NOAH-LSM is the result of the further developments of LSMs, designed for atmosphere applications over the last years and scientific studies like the PILPS project.

Potential evaporation is calculated within the NOAH-LSM using a Penman-based energy balance approach (Mahrt and Ek, 1984) including a stability-dependent aerodynamic resistance. It includes a 4-Layer soil model and a canopy resistance approach of Jaquemin and Noilhan (1990) and Planton (1989). The prognostic variables are the moisture and temperature of the soil layers, water stored on the canopy and snow stored on the ground. Daily surface runoff is computed by the Simple Water Balance (SWB) model (Schaake et al., 1996). The NOAH-LSM computes actual evapotranspiration separately for the following components: Direct evaporation (Eq. A2), evaporation of intercepted water (Eq. A3) and transpiration (Eq. A4).

$$E_{dir} = (1 - \sigma_f) \beta E_p \quad (A2)$$

$$E_i = \sigma_f E_p \left( \frac{W_c}{S} \right)^n \quad (A3)$$

$$E_t = \sigma_f E_p B_c \left[ 1 - \left( \frac{W_c}{S} \right)^n \right] \quad (A4)$$

Besides the green vegetation fraction ( $\sigma_f$ ), the NOAH-LSM is taking the soil water content ( $\beta$ ), the intercepted canopy water content ( $W_c$ ), the maximum canopy capacity ( $S$ ) as well as a plant coefficient ( $B_c$ ) as a function of canopy resistance into account (Chen et al., 1996).

The green vegetation fraction ( $\sigma_f$ ) strongly influences simulation results since it acts as a fundamental weighting coefficient of potential evaporation ( $E_p$ ) within the calculation of all components of evapotranspiration. MM5 uses monthly values of green vegetation fraction ( $\sigma_f$ ) (also known as Fcover) for each grid cell at the model's spatial resolution in order to control seasonal phenological development of vegetation as well as the degree of urbanization and impervious surfaces for each grid cell. It is defined as a function of NDVI (Eq. A5).

$$\sigma_f = \frac{NDVI - NDVI_0}{NDVI_\infty - NDVI_0} \quad (A5)$$

Where  $NDVI_0$  and  $NDVI_\infty$  are the lower and upper 5% of the global NDVI distribution for the whole year and, therefore, describe the signals from bare soil and not-vegetated areas and dense green vegetation respectively (Chen et al., 1996; Gutman and Ignatov, 1997). Since the

$NDVI_{\infty}$  is likely to reach saturation, this approach tends to overestimate  $\sigma_f$  (Richter and Timmermans, 2009). Uncertainties of NDVI due to soil moisture, soil type and colour, dead vegetation and shadow-effects within the plant stand as well as atmospheric effects such as cloud contamination and angular effects of the radiometer field-of-view (FOV) affect satellite-based measurements of the vegetation fraction, making it an unreliable quantity (Bach and Verhoef, 2003; Gutman and Ignatov, 1997; Richter and Timmermans, 2009). Further, the use of the 5th percentile of NDVI for calculating the vegetation fraction assumes a dense vegetation for all pixels in the model domain (Gutman and Ignatov, 1997). The green vegetation fraction concerning this study was gathered by a 5-year time series of NDVI (Chen et al., 1996; Gutman and Ignatov, 1997) from AVHRR (US Geological Survey (USGS)), with a spatial resolution of 10 minutes (18.5 km) and global coverage. It was further generally reduced by 30 percent since it proved to be too high for our simulation area and this reduction helped to improve the simulation of summertime near surface temperature substantially (Pfeiffer and Zängl, 2009).

The canopy treatment represented by the plant coefficient ( $B_c$ ) within  $E_t$  is a function of the canopy resistance ( $R_c$ ), where  $C_h$  is the surface exchange coefficient for heat and moisture;  $\Delta$  depends on the slope of the saturation specific humidity curve;  $R_r$  is a function of surface air temperature, surface pressure, and  $C_h$  (Eq. A6) (Chen and Dudhia, 2001b),

$$B_c = \frac{1 + \frac{\Delta}{R_r}}{1 + R_c C_h + \frac{\Delta}{R_r}} \quad (\text{A6})$$

The canopy resistance ( $R_c$ ) is formulated as follows in the NOAH-LSM (Eq. A7):

$$R_c = \frac{R_{c \min}}{LAI F_1 F_2 F_3 F_4} \quad (\text{A7})$$

, where  $F_4$  is the water-stress function with respect to soil moisture while  $F_1$ ,  $F_2$  and  $F_3$  represent the effects of solar radiation, vapour pressure deficit and air temperature on the canopy resistance. The values of all functions range between 0 and 1; LAI is the leaf area index and  $R_{c \min}$  is the minimum canopy resistance which is set to  $40 \text{ s m}^{-1}$  for the class 'dryland, cropland and pasture' (Jacquemin and Noilhan, 1990; Noilhan and Planton, 1989).

The maximum value of the canopy resistance is set to  $5000 \text{ s m}^{-1}$  for all plants. The LAI does not change with season and for all land use classes of the NOAH-LSM has a value of 4.0. The temperature-stress function is the same for all plants, the optimum transpiration temperature being parameterized with 298 K (Chen and Dudhia, 2001b). The dynamic function of water-stress ( $F_4$ ) is a factor for the availability of soil moisture, however neglecting plant specific parameters (Eq. A8).

$$F_4 = \sum_{i=1}^3 \frac{(\Theta_i - \Theta_w) d_{zi}}{(\Theta_{ref} - \Theta_w)(d_{z1} + d_{z2})} \quad (\text{A8})$$

It is a function of volumetric soil moisture content ( $\Theta$ ) and the soil specific parameters of field capacity ( $\Theta_{ref}$ ) and the wilting point ( $\Theta_w$ ) for the upper three soil layers integrated in the rooted zone with its individual thickness ( $d_{zi}$ ) (Chen and Dudhia, 2001b), parameterized as percentage values of soil moisture.

### 12.1.2. PROMET

PROMET was developed for hydrological river catchment studies on the local and regional scale. It describes processes at the land surface physically based with high detail and complexity using several sub-modules (Figure A4). It conserves mass and energy and closes the energy balance of the land surface. Consequently, it is not calibrated. It was applied in this study with an hourly temporal and 1 km spatial resolution. An extensive model description can be found in Mauser and Bach (2009) and Muerth and Mauser (2012).

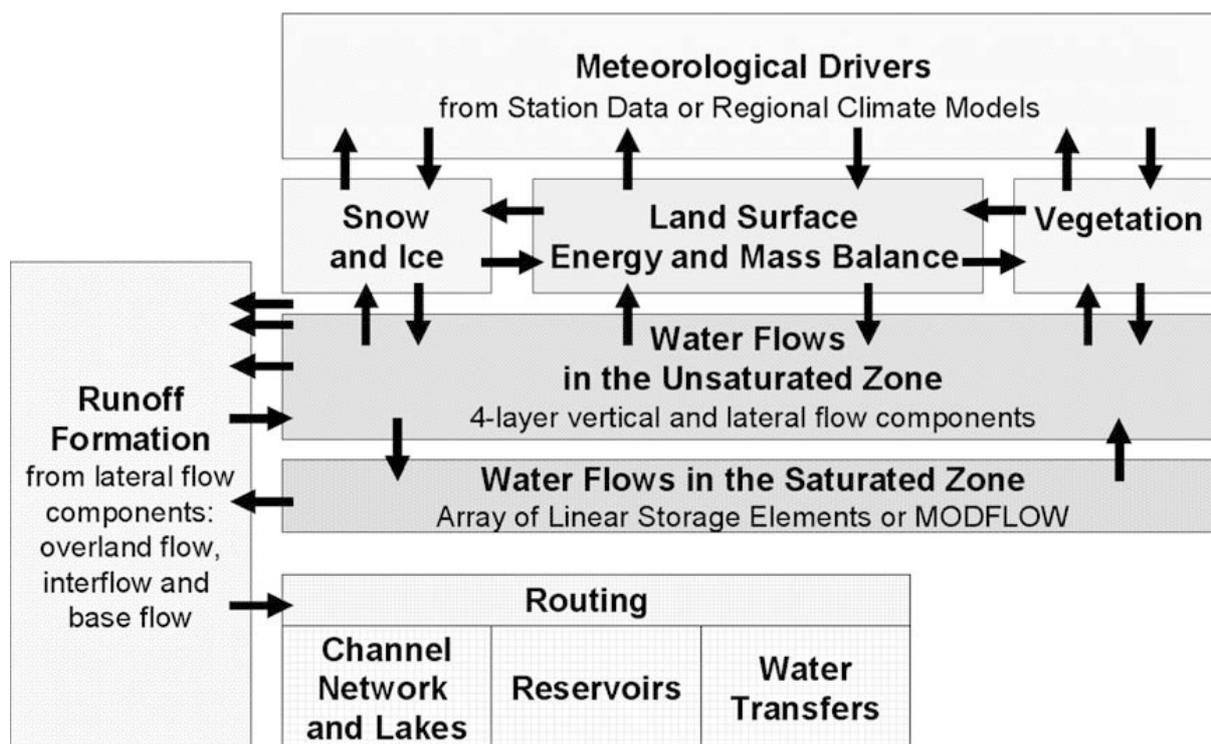

Figure 12.1.1: Model components of PROMET (Mauser and Bach, 2009).

PROMET has already been used in several small and large scale watersheds ranging from a few hundred km<sup>2</sup> to app. 1 million km<sup>2</sup> and has been extensively validated in different regions in the world (Hank, 2008; Koch et al., 2011; Loew, 2008; Loew et al., 2009; Ludwig and Mauser, 2000; Ludwig et al., 2003a; Ludwig et al., 2003b; Marke et al., 2011; Mauser and Schädlich, 1998; Mauser and Bach, 2009; Muerth, 2008; Muerth and Mauser, 2012; Prasch et al., 2006; Prasch et al., 2011; Strasser, 1998; Strasser and Mauser, 2001; Strasser et al., 2007; Weber et al., 2010).

Actual evapotranspiration within the vegetation component of PROMET is simulated using the Penman-Monteith equation (Mauser and Schädlich, 1998; Monteith, 1965; Monteith and Unsworth, 2008), closing the energy balance iteratively (Mauser and Bach, 2009). The water pathway via the soil through the roots into the leaf and passing via the stomata into the laminar and finally the turbulent atmosphere, is driven by the potential difference of water vapour pressure between the soil and the atmosphere, assuming that the atmospheric suction is limited by a number of resistances similar to electrical conductivity (Monteith and Unsworth, 2008). The canopy resistance is calculated for individual plant types following an approach by Baldocchi et al. (1987) and Jarvis (1976).

The stomata resistance ( $R_c$ ) is a function of radiation ( $PAR$ ), temperature ( $F_1$ ), ambient humidity ( $F_2$ ), CO<sub>2</sub> in the atmosphere and the leaf water potential ( $F_3$ ) (Jarvis and Morison, 1981) (Eq. A9).

$$R_c = \frac{R_{c\min}(PAR)}{F_1 F_2 F_3} \quad (\text{A9})$$

PAR is calculated according to the fractions of sunlit and shaded leaf area and the PAR flux densities on the respective leaves (Baldocchi et al., 1987). The relation of temperature, humidity deficit and leaf water potential to the stomata resistance is described with  $F_1$ ,  $F_2$  and  $F_3$  following Jarvis (1976), returning values between 0 and 1. An increase in temperature beyond a plant specific optimum results in an increase of stomata resistance since the plant's stomata will close in order to protect itself against dehydration, which results in a decrease of transpiration. The conductivity is reduced to the minimum stomata conductivity, which is the conductivity of the cuticle.

The inhibition of transpiration due to water stress (Eq. A10) is quantified in PROMET in terms of leaf water potential, which depends in a plant-specific way to the soil water potential ( $\Psi_s$ ) within the rooted soil layers (= root water uptake reduction function).

$$F_3 = ((\Psi_s + R_r) - \Psi_0) * a_\Psi + b_\Psi \quad (\text{A10})$$

The stomatal conductance shows no dependence on leaf water potential below a plant specific threshold ( $\Psi_0$ ) of suction and an approximately linear plant specific decrease beyond (Baldocchi et al., 1987), and takes the resistance of the transition from the soil to the root ( $R_r$ ) into account (Biscoe et al., 1976). The parameters  $R_r$ ,  $\Psi_0$ ,  $a_\Psi$  and  $b_\Psi$  are parameterized for each plant type in PROMET where  $a_\Psi$  describes the plant specific slope and  $b_\Psi$  the plant specific intercept of the function. The soil water potential ( $\Psi_s$ ) as in PROMET is a function of soil type and soil water content following an approach of Brooks and Corey (1964) (Eq. A11).

$$\Psi_s = \Psi_1 \cdot S^{-1/m} \quad (\text{A11})$$

, where  $\Psi_1$  is the air entry tension (bubbling pressure head),  $S$  is the saturation of the effective pore space with water and  $m$  is the pore-size distribution index, which are all parameters available within the soil parameterization of PROMET.

## 12.2. Curriculum Vitae

### Personal

---

Name: Florian Zabel  
Date of Birth: 17.03.1981  
Place of Birth: Munich, Germany  
Degree: Dipl. Geogr. (phys.)  
Email: f.zabel@iggf.geo.uni-muenchen.de

### Scientific career

---

- Since 2010 Collaboration in the Global Assessment of Land Use dynamics on Greenhouse Gas Emissions and Ecosystem Services (GLUES) project.
- 2008-2010 Collaboration in the GLOWA-Danube project (Globaler Wandel des Wasserkreislaufs).
- 2006-2008 Student assistant at the National Committee on Global Change Research (NKGCF).

### School and Education

---

- 2008-2012 Ph.D. studies at the Department of Geography, LMU Munich.
- 2007 Academic degree of graduate physical geographer.  
  
Diploma thesis: "*Vergleichende Analyse skaliertes meteorologischer Eingabedaten der regionalen Klimamodelle CLM, MM5 und REMO für die hydrologische Modellierung im Einzugsgebiet der Oberen Donau*".
- 2001-2007 University studies of physical Geography at the LMU, Munich.  
Subsidiary subjects: Computer Science, Remote Sensing, Chemistry.
- 1991-2000 High-School at the Viscardi-Gymnasium Fürstenfeldbruck
