München, 2017

Erklärung

Diese Dissertation wurde angefertigt unter der Leitung von Prof. Dr. Jochen Herms am Zentrum für Neuropathologie und Prionforschung der Ludwig-Maximilians-Universität und wurde vertreten von Prof. Dr. Rainer Uhl.

Eidesstattliche Versicherung

Ich versichere hiermit an Eides statt, dass meine Dissertation selbständig und ohne unerlaubte Hilfsmittel angefertigt worden ist. Die vorliegende Dissertation wurde weder ganz, noch teilweise bei einer anderen Prüfungskommission vorgelegt. Ich habe noch zu keinem früheren Zeitpunkt versucht, eine Dissertation einzureichen oder an einer Doktorprüfung teilzunehmen.

München, 21.03.2018

Summary

Alzheimer's disease (AD) is a chronic neurodegenerative disease of the central nervous system (CNS) characterized by progressive cognitive decline. AD is the most common cause of all dementia cases worldwide, and as a result of demographic aging the number of affected individuals grows at an alarming rate. The amyloid hypothesis of Alzheimer's disease (AD) emphasizes amyloid- β peptide (A β) as primary cause of the disease, with toxic effects on synapses leading to cognitive decline and memory impairments. Beta site amyloid precursor protein cleaving enzyme 1 (BACE1) as the rate-limiting enzyme of amyloidogenic processing of amyloid precursor protein (APP), is one of the prime drug targets for the treatment of AD. However, despite the development of potent and selective small-molecule BACE1 inhibitors, so far all human clinical trials have failed to rescue the cognitive decline in AD patients. Recent findings indicate that treatment has to be commenced before AD symptoms arise, since in symptomatic patients β -amyloid deposition has already reached a plateau. Moreover, several studies have described dose-dependent adverse effects in animal models. Therefore, it is a central requirement to develop a treatment strategy that is therapeutically effective and at the same time avoids excessive interference with physiological function of BACE1.

In this study, transgenic AD mice were treated at an early stage of β -amyloid pathology with the potent, blood brain barrier penetrating BACE1 inhibitor NB-360. Longitudinal *in vivo* two-photon imaging was performed to repeatedly monitor individual amyloid plaques, presynaptic boutons and axonal dystrophies in living mice. In APPPS1 mice pharmacological BACE1 inhibition

fails to revert but significantly reduces the progressive amyloid deposition and mitigates presynaptic pathology. Notably, the data show that plaque seed formation, rather than the subsequent phase of gradual plaque growth, is most sensitive to BACE1 inhibition. These results imply, that preventive BACE1 inhibitor treatment is required to achieve therapeutic efficacy. For clinical therapy, to exploit the particular susceptibility of plaque formation to BACE1 inhibition, a dosage has to be empirically determined that effectively halts formation of new plaques rather than aiming at halting plaque growth. This strategy might optimally balance potential mechanism-based adverse effects and efficacious reduction of β -amyloid deposition.

Zusammenfassung

Morbus Alzheimer ist eine chronische neurodegenerative Erkrankung des zentralen Nervensystems und äußert sich in progressivem Verlust kognitiver Funktionen und Gedächtnisleistung. Die Erkrankung ist die weltweit häufigste Ursache für Demenz und aufgrund demografischer Alterung in den Industrieländern, nimmt die Zahl der Alzheimer Patienten stetig zu. Der Amyloid-Kaskaden-Hypothese zufolge, wird die Alzheimer Erkrankung durch pathologische Akkumulation und Aggregation des A β -Peptids (A β) ausgelöst. A β wird durch sequentielle enzymatische Spaltung des Amyloid-Vorläuferproteins APP produziert. Die β -Sekretase BACE1 initiiert den ersten Schritt dieses sogenannten amyloiden Prozessierungswegs und ist somit eines der aussichtsreichsten Wirkstoffziele zur Senkung des A β -Spiegels. Im Verlauf der letzten Jahre wurden sehr wirksame und zugleich selektive BACE1 Inhibitoren hergestellt, doch bislang sind klinische Studien daran gescheitert, den progressiven Gedächtnisverlust aufzuhalten. Neueste Erkenntnisse weisen darauf hin, dass die Behandlung bereits vor dem Auftreten der ersten Symptome begonnen werden muss, da in symptomatischen Patienten die Ablagerung von A β in den meisten Fällen bereits abgeschlossen ist. Hinzu kommt, dass in den letzten Jahren vermehrt negative Begleitscheinungen der Behandlung mit BACE1 Inhibitoren in Mäusen bekannt geworden sind. Die entscheidende Herausforderung ist somit, eine Behandlungsstrategie zu entwickeln, welche einerseits die physiologische Funktion von BACE1 nicht zu stark beeinträchtigt, aber zugleich therapeutische Effizienz gewährleistet.

In der vorliegenden Studie wurden transgene Alzheimer Mäuse in einem frühen Stadium der β -amyloiden Pathologie mit dem potenteren BACE1 Inhibitor NB-

360 behandelt. Mittels chronischer *in vivo* Mikroskopie konnten einzelne β -amyloide Plaques, präsynaptische Boutons und axonale Dystrophien in lebenden Mäusen verfolgt werden. Die Behandlung erbrachte zwar keinen Rückgang der A β Ablagerung, konnte jedoch deren Fortschreiten verringern, sowie die progressive axonale Pathologie abschwächen. Insbesondere zeigten unsere Daten, dass die BACE1 Inhibitor Behandlung einen wesentlich größeren Einfluss auf die Bildung neuer β -amyloider Plaques, als auf deren Wachstum hatte. Diese Ergebnisse weisen darauf hin, dass die Behandlung mit BACE1 Inhibitoren präventiv erfolgen muss. Für die klinische Anwendung könnte man sich die besondere Anfälligkeit der Neubildung von Plaques zu Nutze machen und über empirische Versuche einen Dosisbereich bestimmen, welcher ausreicht, die Neubildung von Plaques zu unterdrücken. Diese Strategie könnte zu einer ausgewogenen Behandlung führen, welche die progressive A β Ablagerung verzögert und gleichermaßen das Auftreten von Nebenwirkungen verhindert.

1. Introduction

1.1 Alzheimer's disease

Alzheimer's disease (AD) is a chronic neurodegenerative disease of the central nervous system (CNS) characterized by progressive cognitive decline (1). AD is the most common cause of all dementia cases (2) and the fourth leading cause of death after cardiovascular diseases, cancer and stroke. Currently, about 36 million people are affected worldwide, and as a result of demographic aging the number of affected individuals grows at an alarming rate (3,4). Due to the immense economical and emotional burden for patients, their family and the whole society, it will be one of the main challenges of this century to develop a therapy for AD. To date, more than 100 years after the first description of AD by Alois Alzheimer (5) no medication has proven to delay or halt the progression of the disease in human patients (6). Given the current lack of an effective treatment there is an urgent need in developing and evaluating disease-modifying therapies.

1.1.1 Clinical symptoms and disease etiology

AD etiology can be subdivided into three stages (7):

1. The early stage is characterized by impaired episodic memory – the capability to memorize autobiographical incidents. These deficits are probably due to progressive degeneration of the medial temporal lobe and the hippocampus (8).

1. Introduction

2. In the advanced stage, memory function progressively declines and patients require support from other people. Notably, a rapid deterioration of episodic and semantic memory occurs. The latter includes the whole factual knowledge, like the meaning of words and their relationships in abstract form. In conjunction there is a change in the emotional state and personality of patients.
3. In the final stage, the cognitive capabilities are massively affected. Patients lose the capability to communicate and are physically strongly restricted. In many cases muscles stiffen and reflexes are lost. The most common cause of death is pneumonia, which results from problems to regulate the larynx that leads to swallowing of liquids and food.

The mean lifespan after onset of symptoms is seven years with strong inter-individual variations (9). However, the neurodegenerative process already starts long before the symptomatic stage. In biomarker studies, pathological changes could be detected already 25 years before symptom onset in patients with inherited AD (1).

1.1.2 Neuropathological characteristica

On the macroscopic level AD is characterized by progressive cortical atrophy, mainly affecting medial temporal lobe and associated brain regions. This process can be detected quite early during clinical pathological progression by applying magnetic resonance imaging (MRI) and manifests as dilation of the lateral ventricles (10). On the microscopic level AD is characterized by the presence of intracellular neurofibrillary tangles composed of hyperphosphorylated tau and extracellular cerebral amyloid plaques composed of the 40 – 42 amino acid β -amyloid peptide (11–13). These lesions are thought to be the

primary cause for degeneration of synapses, neuron loss (14) and inflammation (15–17).

1.1.3 Amyloid plaques

The term “amyloid” plaques was coined by the German pathologist Rudolf Virchow and originates from the Latin translation of starch “*amylum*”. In 1854, Virchow was the first to detect plaques, by applying a iodine staining which labels starch (18). Even though it was shown later that amyloid plaques are composed mainly of protein (19,20), the term was maintained for historical reason.

Amyloid plaques arise from aggregation of β -amyloid ($A\beta$) that is produced from sequential proteolytic cleavage of the amyloid precursor protein (APP) (21,22). Plaques are typically of spheric morphology, with a diameter ranging up to 200 μm (23). Generally two types of amyloid plaques can be distinguished. Neuritic plaques have a compact core, composed of amyloid fibrils with characteristic parallel beta-pleated sheet conformation (24). Typically, neuritic plaques are surrounded by reactive astrocytes, activated microglia and dystrophic neurites (25,26). Diffuse plaques are amorphous structures and have no sharply defined outer boundary. These plaques lack a dense core, and instead, $A\beta$ deposition is evenly distributed throughout the whole plaque (26). Unlike neuritic plaques, diffuse plaques are not detrimental to the neuropil. They are not considered as pathological criterium for diagnosis of AD (27), since they are frequently found in cognitively unaffected aged humans.

The β -amyloid pathology typically initiates locally at specific sites and then gradually disperses into adjoining unaffected regions (28–33). The sequential order in which distinct brain regions are affected can be divided in five phases

(33). (1) isocortex, (2) entorhinal cortex and hippocampus, (3) striatum and diencephalon, (4) different nuclei of the brainstem, (5) cerebellum. While neuritic plaques are clearly detrimental to surrounding neuropil, clinical studies have shown that cognitive decline in Alzheimer patients does not correlate well with plaque density nor the total plaque burden (34–36).

1.1.4 Tangles

Neurofibrillary tangles develop due to hyperphosphorylation, misdistribution and ultimate intracellular aggregation of the protein tau (37,38). Native tau has no rigid three-dimensional structure but can adopt different conformations (39). Even though it is difficult to experimentally retrace the conformational changes of tau during the process of aggregation, there is a general consensus about the initiation of tau aggregation. Tau has a lysine-rich subdomain that can bind and thereby stabilize the negatively charged β -tubulin subunit of microtubules (40–44). Due to this characteristic, tau plays an important role in formation of cell protrusions (45), cell polarity (11,46) and regulation of axonal transport (47). Under pathological conditions, the tau protein is hyperphosphorylated (48,49) and binding to microtubules is reduced (50). As a consequence, axonal transport is impaired (51) and tau is aberrantly distributed into the somatodendritic compartment (52,53). Enrichment of tau in the cytosol causes a conformational change into the Alz50-conformation (a specific epitope is detected by antibody Alz50) that promotes aggregation of tau (54). Subsequent posttranslational modifications cause formation of paired helical filaments with β -sheet structure similar to amyloid fibrils (55). These intraneuronal aggregates are designated neurofibrillary tangles and even remain as extracellular deposits after the neuron has perished (52,56). Hyperphosphorylated tau aggregates also develop in dystrophic neurites in proximity to neuritic plaques and are called neuropil threads (57). Similar to sequential spreading of amyloid

pathology, tau pathology also proceeds in temporally and spatially defined manner. The german neuropathologist Heiko Braak divided the progression of tau pathology in six stages (58): (stage I and II) trans-entorhinal and entorhinal cortex, (stage III and IV) hippocampus, (stage V and VI) isocortex. Since tau pathology more reliably correlates with cognitive decline than amyloid pathology (59), this classification by Braak is used as standard for clinical *post mortem* diagnosis for AD (58).

1.1.5 Synaptic failure

AD is characterized by progressive degeneration of synapses and neurons which manifests *post mortem* as strong atrophy of the brain (60,61). The most severely affected brain regions are the hippocampus and anatomically adjoining entorhinal, parietal and frontal cortex (62–64). Loss of presynaptic boutons was revealed by immunohistochemical studies in which a reduction of the presynaptic marker synaptophysin could be detected (65) and is most pronounced in close proximity to amyloid plaque deposits (66–74). In the AD brain, plaques are typically surrounded by swollen, dystrophic neurites (Figure 1) (25,75) and the majority of these peri-plaque dystrophies is presynaptic or axonal in origin (76–81). However, while dendrites rarely form dystrophies, dendritic spines are particularly reduced around plaques (82). Numerous studies have shown that synapses are a structural correlate for learning and memory (83–85). Indeed, the progressive cognitive decline correlates better with synapse loss than any other neuropathological phenotypes (86–88).

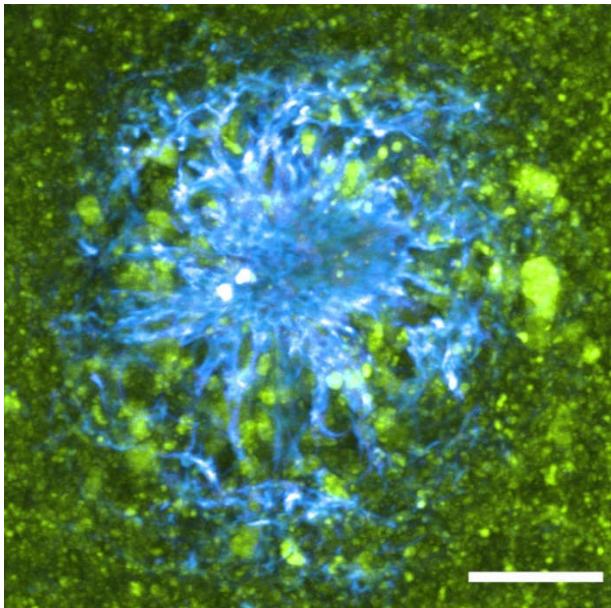

Figure 1. A β plaques are surrounded by axonal dystrophies. Microscopic image of a neuritic plaque from a 7 months old APPS1xVGLUT1^{Venus} mouse (89,90). β -amyloid fibrils were stained with the dye Methoxy-X04 (cyan) and VGLUT1-positive boutons and axonal dystrophies are labelled due to endogenous expression of VGLUT1^{Venus} (green). Scale bar represents 10 μm .

1.1.6 Molecular biology

Due to methodological progress in molecular biology and genetics, knowledge on the pathological mechanisms underlying AD could be greatly expanded in the last three decades. In 1984, for the first time, the biochemists George Glenner and Philip Wong purified and sequenced the main constituent of amyloid plaques – the A β peptide (91). Only three years later, APP was identified as the precursor protein for A β generation (92). In the majority of patients, AD occurs idiopathically without identifiable cause, and only approximately 5% of cases suffer from inherited autosomal dominant type (93). Genetic studies have shown that some patients suffering from inherited AD have point mutations in the APP gene (94,95), which facilitate generation and aggregation of A β and thereby the formation of A β plaques (96,97). These observations lead to the 'Amyloid cascade hypothesis', which states that excessive generation and subsequent deposition of A β in the brain is the causal initiator of a cascade of pathological events that ultimately lead to AD (98).

1.1.7 Proteolytic processing of APP

APP is a ubiquitously expressed transmembrane glycoprotein of type 1 (95). In mammals, APP together with homologous amyloid precursor like proteins 1 and 2 (APLP1 and APLP2) constitute the APP-protein family. However, only APP contains the A β domain necessary for A β plaque formation (99–101). In humans, the APP gene is localized on chromosome 21 (92,102–104) and is present in three different splice variants of 695, 751 or 770 amino acids. While APP751 and APP770 are expressed in almost all tissues, the variant APP695 is primarily expressed by neurons and localizes to synapses, dendrites and axons (105–109). After initial translation, APP traffics along the secretory pathway and matures by posttranslational modifications, including glycosylation, phosphorylation and sulfation (110). Subsequently, the APP holoprotein is proteolytically cleaved either along the amyloidogenic pathway or the non-amyloidogenic pathway (111).

In the non-amyloidogenic pathway, APP is initially cleaved by the metalloprotease ADAM10 (a disintegrin and metalloproteinase 10) within the A β domain between amino acids 16 and 17 (112). This cleavage generates the soluble ectodomain sAPP α (113,114) and the membrane bound carboxy-terminal fragment, α CTF (C83). α CTF is further processed by γ -secretase, (115) yielding the amyloid precursor protein intracellular domain (AICD) and a series of short hydrophobic peptides including A β 17–40 and A β 17–42, which are collectively called p3 fragments (116). Outside the CNS, APP is preferentially cleaved by α -secretase (117–119).

The amyloidogenic pathway (Figure 2), leads to the generation of A β and is initiated by proteolytic cleavage of APP by β -site APP cleaving enzyme 1 (BACE1). BACE1 processing of APP takes place in endosomes, since their acidic environment offers optimal conditions for enzymatic activity of BACE1

1. Introduction

with an optimal pH of approximately 5 (120,121). Proteolytic cleavage of APP by BACE1 is the rate-limiting step in the cascade and results in the generation of a large soluble extracellular fragment commonly referred to soluble APP- β (sAPP β) which is released into the extracellular space and a membrane anchored C-terminal fragment (CTF β or C99). CTF β is finally cleaved by the γ -secretase complex. γ -secretase is a multi-subunit aspartyl protease that consists of nicastrin, the stabilizing factor APH-1, presenilin-enhancer 2 and the catalytic subunits presenilin-1 and presenilin-2 (122). γ -secretase cleaves APP-CTF β and many other type I transmembrane proteins within their transmembrane domains (123–125). CTF β processing results in the generation of the membrane-anchored nuclear-localizing fragment AICD and A β -peptide which is released into the extracellular space (110,126).

The initial cleavage by γ -secretase takes place within the transmembrane domain close to the cytoplasmic border of the membrane and releases AICD. Subsequently, the remaining long A β fragment is successively cut producing A β -peptides ranging from 37 to 43 amino acids (127). Mutations in γ -secretase and APP destabilize the intermediary enzyme-substrate complex, leading to enhanced dissociation and thereby release of longer and more amyloidogenic peptides (128). Thus, sequential cleavage of APP by γ -secretase is a key determining feature that can increase an individual's risk of developing AD. The different A β species have different conformational characteristics (129). In comparison to the most abundant variant A β ₄₀, the variant A β ₄₂ has a tendency to aggregate into amyloid fibrils (130,131). Indeed, the main constituent of fibrillar A β in neuritic plaques is A β ₄₂ (132). In contrast, shorter A β peptides including the predominant A β ₄₀ species, inhibit A β aggregation and deposition (133,134).

1.1.8 Amyloid cascade hypothesis

Accumulation of A β in protein aggregates triggers numerous pathophysiological changes that ultimately lead to cognitive dysfunction (135). The amyloid cascade hypothesis is the prevailing theory that describes the sequence of pathological changes that lead to AD (98,136,137) and was postulated in 1991 by John Hardy and Dennis Selkoe. The amyloid cascade hypothesis puts forward the accumulation of A β as initial and causative event. The aggregation of A β has detrimental effect on synapses and causes gliosis as well as hyperphosphorylation of tau, leading to generation of intracellular tau fibrils. Finally, the cascade results in progressive synaptic and neuronal degeneration and thereby culminates in dementia with characteristic plaque and tangle pathology (138).

The observation that A β is the main constituent of β -amyloid plaques and cerebral angiopathies (91,139) does not causally link A β pathology to AD. However, genetic studies provide strong indications for a clear correlation. In Down syndrome patients the chromosome 21, which contains the APP gene, is present three times, resulting from a chromosome aberration. In these patients, A β production and thereby β -amyloid deposition are enhanced. Almost all cases develop clinical symptoms of AD until 55 years of age (136,140–142). Up to now, all mutations linked with the inherited form of AD are related to the cellular machinery implicated in A β production (143) and either occur in the APP-gene (95,144) or in catalytical subunits of PS1 and PS2 of the γ -secretase complex (145). In addition, mutations within the β -cleavage site of APP that reduce the production of A β confer protection against cognitive decline in the elderly (146) and knockout of the *Bace1* gene abrogates amyloid pathology in AD mice (147). The only genetic risk factor for AD identified so far is Apolipoprotein E4 (ApoE4). The protein is secreted by glia and is essentially

1. Introduction

involved in binding and clearance of A β from the CNS (148). Recently, it was shown that ApoE4 exacerbates neuronal A β production via a signal transduction pathway whereby ApoE activates a non-canonical mitogen-activated protein (MAP) kinase cascade that enhances APP transcription and thereby A β production (149).

The amyloid cascade hypothesis is based on the assumption that the occurrence of tau pathology is a consequence of β -amyloid deposition. This notion is supported by results from patients with frontotemporal dementia, a neurodegenerative disease characterized by massive tau pathology despite lack of β -amyloid pathology (150,151). This indicates that pathological accumulation of tau *per se* is neurotoxic but cannot initiate A β pathology (136,152). Conversely, in tau overexpressing mouse models, tau pathology is aggravated by coexpression of mutated human APP (153). Further evidence on the interplay between A β and tau pathology was obtained from experiments in transgenic mouse models and cell culture. Genetic knockout of tau ameliorates A β induced learning deficits, reduced long-term potentiation (LTP) and nerve cell loss (154–156). The molecular mechanisms of tau induced synaptotoxicity of A β are still under investigation. A β aggregation triggers hyperphosphorylation of tau via the CAMKK2-AMPK signaling cascade (calcium/calmodulin-dependent protein kinase kinase 2, 5' adenosine monophosphate-activated protein kinase) and thereby causes mislocalization of tau to the dendritic compartment (157). Aberrant localization of tau in dendritic spines has been claimed to lead via kinase Fyn to hyperphosphorylation of NMDA-receptors (N-Methyl-D-Aspartate). Subsequently, excessive release of neurotransmitter glutamate results in excitotoxicity and degeneration of synaptic terminals (158,159).

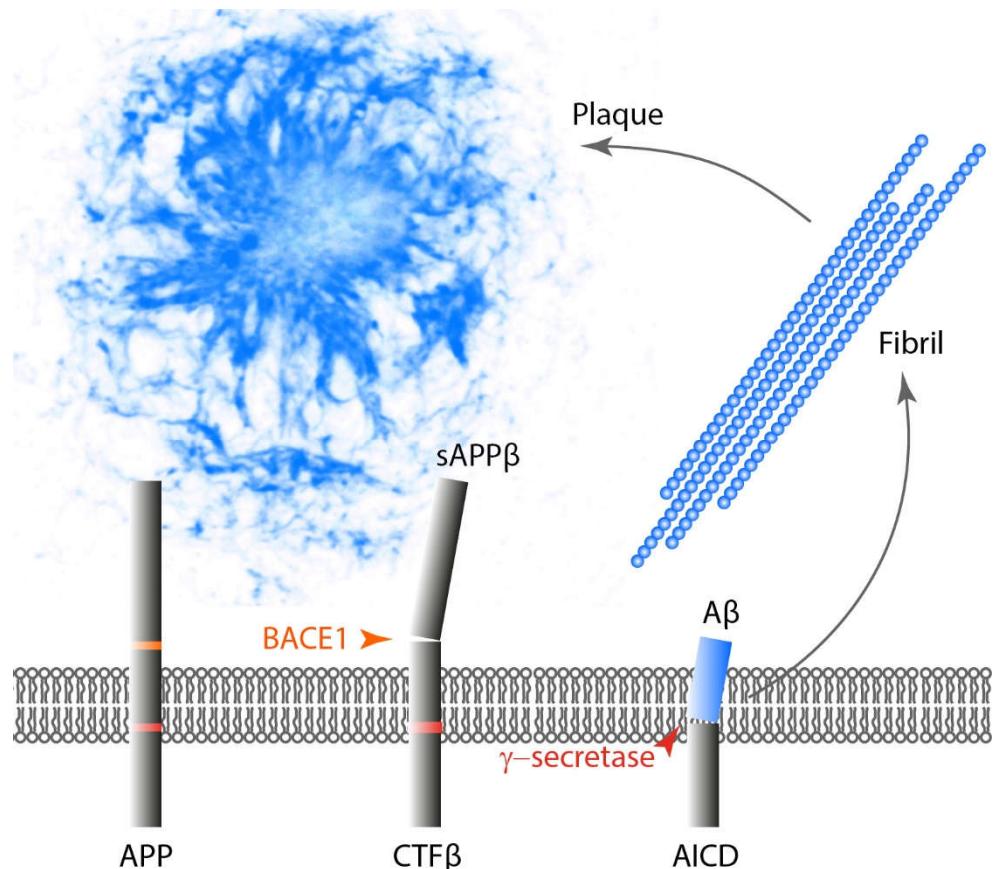

Figure 2. Illustration of the amyloid cascade hypothesis. Proteolytic cleavage by BACE1 initiates amyloidogenic processing of APP and generates CTF β and sAPP β which is released into the extracellular space. CTF β is further processed by γ -secretase, resulting in the formation of A β and AICD. A β and in particular the A β 42 variant, is prone to aggregation, which results in the formation of A β fibrils and ultimately plaques.

1.2 BACE1

BACE1 is an aspartate endopeptidase and catalyzes the initial and rate-limiting step of amyloidogenic processing of APP to form the toxic β -amyloid peptide (A β). Therefore, BACE1 is one of the primary therapeutic targets to lower the cerebral A β level in AD patients. The central role of BACE1 in processing of APP was discovered for the first time in 1999 by five different research groups simultaneously (160–164). In these studies, a second aspartate-endopeptidase (BACE2) was identified with 64% amino acid sequence homology. Both

endopeptidases can be detected in diverse tissues, but BACE1 is mainly produced in the brain (162,164,165). Also, BACE1 but not BACE2 is the relevant β -secretase *in vivo* for the processing of APP (166). The catalytic domain of BACE1 enzyme has two characteristic (DT/SGS/T) motifs similar to the pepsin family of aspartate proteases (167). However, in contrast to this family of proteases, BACE1 is a type I transmembrane protein. The C-terminus reaches into the cytosol and the N-terminus which contains the active center is located on the luminal side.

1.2.1 Physiological function

Within the plasma membrane, BACE1 localizes to lipid rafts (168) and specific lipids in these cholesterol-rich microdomains can promote activity of BACE1 (168). Intracellularly BACE1 localizes to diverse subcellular organelles. BACE1 is initially synthesized as an inactive pro-enzyme and is converted into the active form in the trans-Golgi network (169,170). The transport of BACE1 in the endosomal-lysosomal system or incorporation into lipid rafts is regulated through phosphorylation and palmitoylation (171,172). The enzyme has maximal catalytical activity at low pH (pH 4.5 – 6.0) in the acidic lumen of the trans-Golgi network and endosomes (173). Previous studies have shown that BACE1 and APP interact in endosomes (173) and the application of compounds that increase endosomal pH effectively inhibit A β production (174). Thus, the majority of APP processing takes place in endosomes. The past decade has revealed numerous substrates of BACE1, including 33 neuronal proteins. Thus, BACE1 is one of the most important sheddases in the nervous system (175). The substrates can be divided according to their physiological function into two different categories. The first group are proteins with a synaptic function. The other group are proteins that interact with the

extracellular matrix of astrocytes and oligodendrocytes and thereby regulate growth of axons (167).

BACE1^{-/-} mice are viable and fertile. However, due to the important role of BACE1 in synaptic function, *Bace1* gene knockout leads to diverse neurological phenotypes, including impaired learning and memory, epileptic seizures, locomotor hyperactivity and schizophrenia-associated behavioral changes (176–178). Pharmacological inhibition of BACE1 decreases spine turnover and total spine density, which indicates a critical role of BACE1 in structural and functional synaptic plasticity in mice (179,180).

The complex phenotypes of *Bace1*^{-/-} mice are at least partly mediated by the BACE1 substrates Sez-6 (seizure-related gene 6) (181) and the Nav β-subunit (182). Sez-6 is a type 1 membrane protein that localizes to dendrites and is predominantly cleaved by BACE1. Sez-6 knockout mice have reduced spine density and impaired excitability of pyramidal neurons in cortical layer V (181). The structural and functional synaptic plasticity is primarily mediated via BACE1 mediated cleavage of Sez-6 (180).

Epileptic seizures in *Bace1*^{-/-} mice are probably a consequence of reduced processing of the Nav β-subunit, that controls expression and surface localization of sodium channels (183,184). As a result, the density of voltage gated sodium channels is increased in *Bace1*^{-/-} mice which causes increased neuronal excitability and thus increased susceptibility to epileptic seizures.

Among the BACE1 substrates that are involved in regulation of axonal growth, especially the cell adhesion protein CHL1 (close homolog of L1) is well characterized. CHL1 is a type 1 membrane protein that is sequentially cleaved by ADAM8 (A Disintegrin and metalloproteinase domain-containing protein 8) (185) and BACE1 (175). The soluble ectodomain can interact with Neuropophilin-

1. Introduction

1 und Semaphorin 3A, and thereby influences axonal targeting (186,187). As a result, *Chl1* knockout mice as well as *Bace1^{-/-}* mice have impaired axonal connectivity of hippocampal mossy fibers within the infrapyramidal bundle. Additionally, the total length of the infrapyramidal bundle is reduced by approximately 30% in *Bace1^{-/-}* mice (188). Since the length of the infrapyramidal bundle is correlated with memory performance in mice (189), this might at least in part account for the cognitive deficits in *Bace1^{-/-}* mice.

Also in the peripheral nervous system, numerous functions of BACE1 have been described. Genetic ablation of the *Bace1* gene causes hypomyelination of nerves in mice (190). This effect is due to reduced proteolytic processing of the BACE1 substrate NRG1 (Neuregulin 1) isoform type III (190), which plays an important role in early postnatal myelination (191). NRG1 type I is also processed by BACE1. Since NRG1 type I has an important function in the formation of muscle spindles, a reduction of NRG1 type I processing causes reduced formation of muscle spindles in *Bace1^{-/-}* mice (192). This effect could be reproduced by pharmacological inhibition of BACE1 in adult wild type mice (192). BACE1 mediated processing of NRG1 type I is not only required for the formation of muscle spindles during their development but also for their maintenance in adulthood. Future clinical trials will reveal whether pharmacological BACE1 inhibition causes a similar phenotype in humans.

1.2.2 Pathophysiology of BACE1 in AD

In the AD brain, amyloid plaques are surrounded by swollen presynaptic dystrophic neurites that are enriched with BACE1 (78,81,193,194). This excessive accumulation of BACE1 might be the reason for the two-fold increased BACE1 levels in brains of AD mice and AD patients compared to healthy individuals (195–200). One possible mechanism for this aberrant localization has been brought up recently by Gowrishankar et al. (77).

According to the hypothesis of this work, A β causes microtubule disruption and motor protein mis-localization by an as yet undefined cascade (76,77). Since BACE1 degradation occurs via the lysosomal pathways (201,202) and therefore depends on retrograde transport to the cell body, a local disruption of microtubules and motor protein mis-localization would impair lysosomal maturation. Consequently, BACE1 and other proteins accumulate in peri-plaque dystrophic neurites (76,77). Excessive enrichment of BACE1 in the proximity of plaques might cause a vicious pathogenic cycle (203). According to this hypothesis BACE1 increases local A β production at plaques and thereby accelerates amyloid deposition even more.

1.3 Therapeutic approaches

The existing AD drugs are just symptomatic therapies, such as the acetyl-cholinesterase inhibitors and the N-methyl D-aspartate receptor antagonist memantine. Both cannot stop the progressive neurodegeneration but rather delay progression by about 3 months. Alternatively, epidemiological studies and experiments in transgenic mice have shown that 'lifestyle' interventions – such as a healthy diet and physical or cognitive exercise – can reduce the incidence of dementia and dementia-related biochemical changes in the brain (204,205). However, efficacy of current medication is limited to the very early stages of the disease and only provides symptomatic relief.

The amyloid cascade hypothesis has led to the identification of therapeutic targets for treatment or prevention of AD and provides the rationale for the current main focus of the pharmaceutical industry to target A β aggregates. The three proteases that are involved in APP processing, namely α -secretase, BACE1 and γ -secretase, are of particular interest, since they can be targeted by small molecule compounds *in vitro* and *in vivo*.

1. Introduction

Enhancing processing of APP by α -secretases is protective in the context of AD because the enzymes cleave within the A β sequence and thereby prevent the production of A β (206,207). However, ablation of many genes that code for α -secretase have turned out to be lethal (206–208). For example, deletion of ADAM10 is lethal in mid-gestation (208). So far, drugs that directly activate α -secretase have not been developed, and thus it is unclear if this strategy is free of adverse side effects and if it might attenuate AD symptoms.

γ -secretase inhibitors decrease A β production in human and mouse brains, and chronic administration decreases A β deposition in APP mouse models (209–212). However, since γ -secretase cleaves numerous transmembrane proteins, mechanism-based adverse effects pose a major obstacle for the successful clinical development of these compounds. For example, γ -secretase processing of Notch1 is crucial for Notch signaling (213) and deletion of PS1 is embryonically lethal in mice (214,215). γ -secretase modulators alter the profile of A β peptides produced by γ -secretase activity *in vitro* and *in vivo* (216,217). Such compounds can selectively reduce the levels of A β 42 and can be safely administered in the long term (218). However, so far clinical attempts failed to rescue the cognitive decline.

1.3.1 Pharmacological inhibition of BACE1

There are several indications that BACE1 inhibition therapy should be beneficial for the treatment of AD. Discovery of the protective APP point mutation Ala673Thr indicates that life-long reduction of A β production by 40% might suffice to prevent AD (219). Additionally, genetic ablation of *Bace1* in transgenic APP overexpressing mice, blocks the production of A β and thereby β -amyloid deposition as well as plaque-associated pathology (147,220,221). Initial studies of *Bace1*^{−/−} mice did not detect developmental or behavioral impairments, nor histological alterations (222), which raised the hope that

inhibition of BACE1 might be free of adverse effects. Over the course of several years various inhibitors were developed. Initial peptide inhibitors that modelled the active center of BACE1, effectively and specifically inhibited BACE1 activity *in vitro*. However, these compounds were too large to pass the blood brain barrier (223). The development of small-molecule non-peptide inhibitors solved this problem (224) and consequently, several BACE1 inhibitors have entered human clinical trials (225–228). Small-molecule BACE1 inhibitors effectively lower brain A β levels (225,229,230) and can reduce plaque burden in mice (231–234). However, two clinical trials have failed so far due to unspecific side effects (6) or lack of efficacy, as documented by the recent failure of the phase 2/3b EPOCH trial of verubecestat (ClinicalTrials.gov identifier NCT01739348). The lack of success may relate to the timing of the intervention. Current trials were performed with mild to moderate dementia cases (235). However, PET (positron emission tomography) studies in combination with amyloid binding radioactive marker Pittsburgh Compound B have shown that in humans, β -amyloid deposition already commences decades before the manifestation of clinical symptoms (1,236–238). Thus, at a stage when amyloid deposition has already reached an asymptote of accumulation, A β lowering drugs might have no more impact. Also it is unclear whether at such a late stage A β -induced pathology is the main mediator of toxicity or whether other toxic mediators would even persist in the absence of amyloid pathology. The current consensus is that at late stage progressive pathology is already so much advanced that it can not be stopped anymore (239). For future AD therapy with A β lowering drugs it is therefore of utmost importance to start therapy at an early stage of β -amyloid pathology (240–242).

1.3.2 Mechanism-based side effects of BACE1 inhibition

Besides optimizing the timing of BACE1 inhibitor treatment, one of the most important prerequisites for successful therapeutic application will be to determine the appropriate BACE1 inhibitor dosage. *Bace1^{-/-}* mice display complex neurological phenotypes, including growth retardation (243), retinal pathology (244), memory deficits (220,221,245), hypomyelination (246,247), seizures (248–250), axon guidance defects (251–253), and schizophrenia-like behaviors (254). The variety of phenotypic alterations in *Bace1^{-/-}* mice indicates that therapeutic BACE1 inhibitor treatment might cause health issues. However, it is unclear whether adverse effects observed in *Bace1^{-/-}* mice also translate to humans. *Bace1^{-/-}* mice completely lack BACE1 enzymatic activity at any developmental stage. Thus, some of the adverse effects might be due to a critical role of BACE1 in development and might not be relevant in adulthood. For example, myelination is an early process that has already completed in adulthood (255) and thus, characteristic hypomyelination in *Bace1^{-/-}* mice clearly is a developmental phenotype. Such reports urge caution against overinterpreting the relevance of *Bace1* deletion data to the outcome of pharmacological inhibition of BACE1. In contrary, formation of muscle spindles is a continuous process that occurs over the whole life span and is affected not only in *Bace1^{-/-}* mice, but also in BACE1 inhibitor treated adult wildtype mice (192). Therefore, this phenotype might also occur in Alzheimer patients (167). Additionally, pharmacological BACE1 inhibition in adult wildtype mice induces rapid and prolonged decrease in spine turnover and spine density after a treatment period of 14 days (179,180). In light of these mechanism-based adverse effects of BACE1 inhibition in mice, it will be critical to minimize BACE1 inhibitor dosage as much as possible. However, there are clear indications that partial inhibition of BACE1 can be therapeutically effective, if

the treatment is initiated early enough. Life-long reduction of A β levels by 40% results in 5- to 7-fold reduced risk of developing AD (146) and a slight reduction of A β levels by 12% in *Bace1^{+/-}* mice reduces total A β deposition by 50% in aged mice (256). Thus, moderate inhibition of BACE1 might suffice to effectively reduce A β levels and still avoid excessive mechanism-based adverse effects (167). In conclusion, the most challenging question for the clinical development of BACE1 inhibitors concerns the stage of Alzheimer's disease at which to treat for optimum efficacy and the appropriate dosage that balances clinical safety and therapeutic efficacy.

1.4 Intravital microscopy

Two-photon intravital microscopy is an imaging technique that enables to visualize various biological processes in living organisms. The technique proved especially useful for the investigation of neurobiological questions. For example, the technique enabled for the first time to image the structural and functional plasticity of neuronal networks *in vivo* and to correlate it with environmental stimuli. The technical development of intravital microscopy was a result of innovative technical milestones in diverse scientific sectors, such as physics, genetics and biochemistry.

1.4.1 Fluorescence microscopy

Brain tissue consists of small and tightly packed biological structures. By applying serial section scanning microscopy, Kasthuri et al. showed that a 1,500 μm^3 cubic volume of brain tissue (equivalent to a cube of 11.4 μm edge length) contains 193 dendrites, 1407 axons and 1700 synapses (257). Initially, this dense allocation of individual substructures in brain tissue hampered investigating the intricate morphology of neurons. The initial breakthrough was

1. Introduction

the development of silver staining by Ramón Cajal, because it allowed to selectively visualize separate neurons and their synapses. However, such sparse histochemical labelling requires chemical processing of the specimen and is thereby limited to *post mortem* tissue. The discovery of fluorescence was a key finding that allowed direct visualization of biological structures in living tissue. In 1908, August Köhler was the first to describe a new microscopical method „luminescence microscopy“ (258) which is nowadays known as fluorescence microscopy. Köhler showed that some stainings – so called fluorophores – emit light when excited at a certain wavelength. The spectrum of emitted light is shifted to longer wavelengths as compared to the excitation spectrum. This phenomenon was coined Stokes-shift after the discoverer George Stokes (259) and is illustrated in Figure 3 by a Jabłoński-diagram (260,261).

Upon absorption of a photon of sufficient energy by a chromophore an electron is excited from the lowest-energy ground state to an excited higher-energy state. However, this excited state is energetically unstable causing the electron to return to the initial ground state within 1 to 10 nanoseconds. Spontaneous transition from the first excited state (S_1) back to the ground state (S_0) with simultaneous emission of a photon is called fluorescence. During this process energy is also released by vibrational relaxation and therefore the emitted photon has lower energy and therefore longer wavelength as compared to the excitation light (Figure 3). Fluorescence microscopy has enabled to directly visualize certain organic compounds due to their intrinsic fluorescence. For example, the autofluorescence of coenzyme nicotinamide adenine dinucleotide (NADH) and nicotinamide adenine dinucleotide phosphate (NADPH) allows to determine the redox state of a cell, since the oxidized versions NAD^+ and $NADP^+$ show reduced fluorescence (262). Additionally, endogenous fluorescence of mitochondrial flavoproteins allows to measure

activity of neurons, since flavoproteins have green autofluorescence under aerobic oxidation (263).

While the discovery of fluorescence allowed visualization of biological structures in the living brain it was the development of genetically encoded fluorophores that immensely increased opportunities to investigate biological processes. In 1962, the biochemist Osamu Shimomura and his colleagues isolated the chemiluminescent protein GFP (green fluorescent protein) from the jellyfish *Aequorea victoria* (264). 30 years later the gene for GFP could successfully be cloned and expressed in different species (265–267). For the discovery and development of GFP Osamu Shimomura, Martin Chalfie and Roger Y. Tsien won the nobel prize for chemistry 2008. GFP expression can be applied to investigate localization, interaction and dynamics of diverse proteins. Expression under a specific promoter allows to observe gene activity in individual cells (268). For the *in vivo* analysis of neuronal structures, transgenic mice have been generated that express GFP or spectral variants under control of specific promoters. For example, in the GFP-M mouse, enhanced GFP (eGFP) is expressed by the pan-neuronal promoter Thy-1.2 (269). As a result of random insertion of the transgene in the genome, only specific neuronal groups express the fluorophore. This results in a sparse labelling of individual neurons, similar to a Golgi staining. Another example is the VGLUT1^{Venus} model which expresses the Vesicular GLUtamate Transporter 1 (VGLUT1), fused to the fluorescent protein Venus under VGLUT1 endogenous promoter (90). This model enables to visualize presynaptic boutons and is described in detail in the following subsection.

Conventional fluorescence microscopy is only partially suited for intravital microscopy of neurons. The high lipid fraction of axonal myelin causes strong scattering of excitation and emission light (270), which limits optical access only

to the superficial cortical layer. This shortcoming was substantially improved by the introduction of two-photon microscopy in 1990 by Winfried Denk (271).

1.4.2 *In vivo* two-photon microscopy

The nonlinear optic effect of two-photon (2P) excitation was already postulated in 1931 by Maria Göppert-Mayer (272). Two-photon excitation occurs when two photons coincide quasi-simultaneously on a fluorescent molecule. These photons must have approximately twice the wavelength that is necessary for excitation by a single photon. The probability for non-linear excitation is very low, but increases proportional with the square of light intensity. Therefore, to obtain measurable 2P excitation high photon density in the range of several kW/cm² has to be generated. Such high peak power can be obtained with pulsed lasers (light **a**mplification by **s**timulated **e**mission of **r**adiation). For example titanium-sapphire (Ti:Sa) lasers can generate very short (<100 femtoseconds), intensive light pulses of defined wavelength at a rate of 80 MHz. Since the light is not emitted continuously but in the form of extremely short pulses, a peak power of several 100 kW can be achieved at a low mean power of 2.5 W. This ensures high density of photons without damaging the specimen.

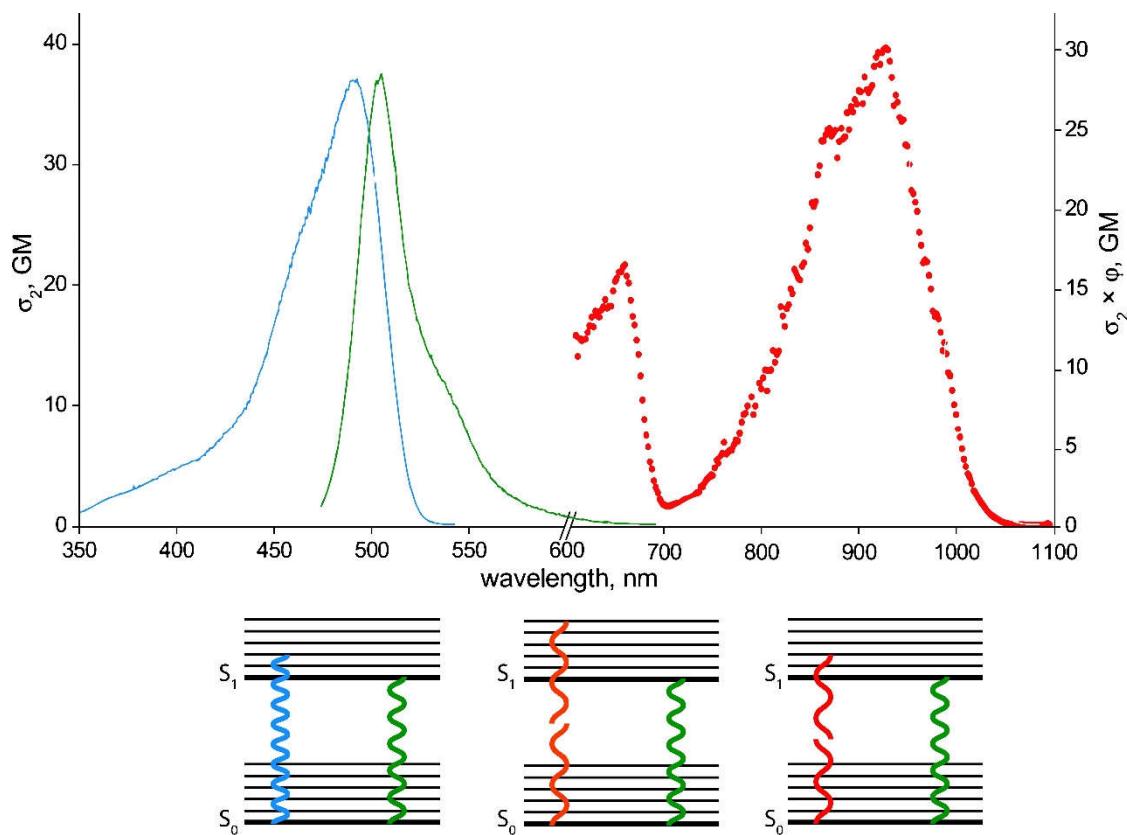

Figure 3. Simplified Jabłoński-diagram for illustration of one-photon versus two-photon excitation for the fluorophore eGFP. For one-photon excitation a single photon (cyan wave) carries sufficient energy to excite the fluorophore to the excited higher-energy state S_1 . Upon transition back to the initial ground state S_0 , a photon of slightly lower energy as compared to the excitation photon is emitted (green wave). For two-photon excitation, two photons each confer half the energy required for one-photon excitation. This nonlinear optic effect requires the photons to coincide quasi-simultaneously on the fluorophore and requires high photon densities. Since S_1 consists of different energy substates, excitation can occur within a range of wavelengths. While the one-photon excitation spectrum usually has one maximum, the two-photon spectrum normally has two maxima. Adapted from Drobizhev et al. (273).

2P microscopy has crucial advantages over conventional laser scanning microscopy. Due to the non-linear optical effect, fluorescence excitation is restricted to the focal spot which provides intrinsic optical sectioning within the axial dimension. In contrast to one-photon excitation – in which the whole light cone is excited – 2P excitation generates no out-of focus excitation. This minimizes photobleaching and phototoxicity. In addition, for 2P excitation

photons of longer wavelength and thereby lower energy can be used which is scattered and absorbed less in neuronal tissue and enables deeper penetration up to 800 µm into the brain (271,274).

To gain optical access to the brain of mice a cranial window has to be implanted onto the skull. Different approaches have been described, the thinned skull (275) and the open skull (276) preparation. For the thinned skull method the skull is carefully thinned with a dental drill until only an approximately 20 µm thin transparent layer of skull is left. Such an optical window is limited in size to 0.1 to 0.3 mm² and the remaining thin layer of skull causes considerable photon aberration limiting the penetration depth. For chronic imaging over long time periods the preparation has to be repeated due to regrowth of bone. In most cases this is only possible for three to four times, since the skull loses transparency over time.

For the open skull preparation, a circular piece of the skull with a diameter from 3 to 5 mm is completely removed and replaced by a glass window. This preparation allows chronic imaging of brain tissue up to a depth of 800 µm for time periods of up to more than one year (277). This approach is considerably more invasive than the thinned skull procedure and causes activation of microglia and astrogliosis. However, the immune reactions normally subside within 3 to 4 weeks after surgery (276).

1.5 VGLUT1^{Venus} mouse model

VGLUT1^{Venus} mice express the Vesicular GLUtamate Transporter 1, fused to the fluorescent protein Venus under VGLUT1 endogenous promoter (90). VGLUT1 is a transmembrane protein localized in presynaptic vesicles and has the function to uptake glutamate into these vesicles. An average synaptic

vesicle (Figure 4a) contains approximately 9 copies of VGLUT1 (278). Hence, in VGLUT1^{Venus} mice all glutamatergic, VGLUT1 positive boutons are fluorescently labeled (Figure 4b). Since the fusion gene replaces VGLUT1 through homologous recombination at the endogenous *vglut1* locus the intensity of emitted fluorescence reflects the amount of VGLUT1 vesicles. VGLUT1^{Venus} mice are viable and fertile. The fusion protein was shown to be fully functional in these mice, since it retains the ability to interact specifically with EndophilinA1 and shows the same glutamate uptake efficacy as WT VGLUT1 (278).

2. Results

2.1 NB-360 reduces soluble A β levels

To assess the efficacy of the BACE1 inhibitor NB-360 (233), APPPS1 mice (89) were fed with food pellet containing NB-360 or vehicle, starting at an age of six weeks. After two weeks of chronic treatment, soluble A β 40 and A β 42 levels were determined via ELISA. The age was chosen to obtain brain tissue before initiation of β -amyloid deposition, in order to exclude contamination by deposited fibrillar A β . NB-360 treatment reduced soluble A β 40 and A β 42 levels in the forebrain by 80% and plasma A β 40 levels by 70% (Figure 5).

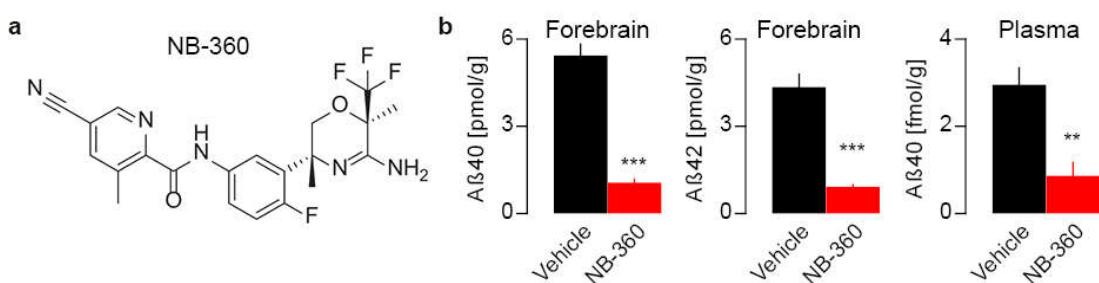

Figure 5. BACE1 inhibition significantly reduces A β 40 and A β 42 levels. (a) Molecular structure of NB-360. (b) In six weeks old mice treated for 14 days *ad libitum* with food pellets containing NB-360 (0.25 g/kg) the levels of A β 40 and A β 42 are significantly reduced by 80% in forebrain and by 70% in plasma. Data presented as mean \pm SEM with ** p < 0.01; *** p < 0.001; n = 6; (*t*-test).

2.2 Concurrent imaging of β-amyloid deposition and synaptic pathology

The question was addressed whether pharmacological interference with A β generation beneficially influences amyloid plaque burden and plaque-associated synaptic pathology. For this, chronic *in vivo* two-photon imaging of Methoxy-X04 stained amyloid plaques and glutamatergic boutons was performed in APPPS1xVGLUT1^{Venus} mice (Figure 6a). The somatosensory cortex was imaged weekly from 3 to 7 months of age and NB-360 or vehicle treatment was initiated at 4 months of age (Figure 6b). Individual plaques were tracked in consecutive imaging time points (Figure 6c).

2. Results

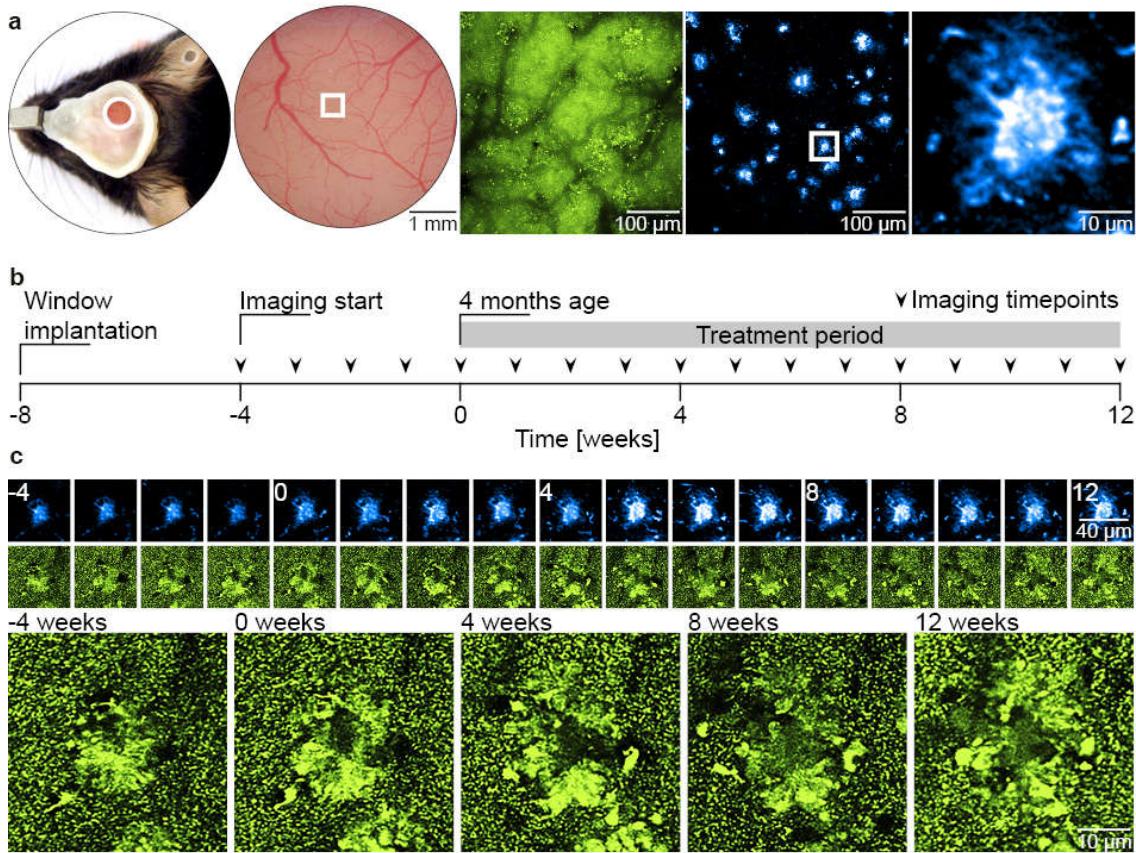

Figure 6. *In vivo* two-photon imaging of plaques and associated synaptic pathology. (a) APPPS1xVGLUT1^{Venus} mice were implanted a cranial window to perform chronic *in vivo* two-photon imaging of somatosensory cortex. (b) Mice were reimaged repetitively in weekly intervals starting from 3 months of age for up to 16 weeks. After 4 time points of baseline imaging mice were administered BACE1 inhibitor or vehicle food pellet. (c) In the same region of interest Methoxy-X04 stained β -amyloid plaques and VGLUT1^{Venus} positive glutamatergic boutons were repetitively imaged.

2.3 BACE1 inhibition slows down β -amyloid deposition

In each mouse approximately 80 plaques were analysed and time point of first appearance and changes in size were quantified over time (Figure 7a). As a result of spherical aberration, plaques seem artificially elongated in axial direction. Thus, for determination of plaque size the largest extension in XY of

each individual plaque was determined and – assuming a spherical shape of plaques (279) – the radius was calculated as $radius = \sqrt{area/\pi}$ (Figure 7b, c). Subsequently, growth of individual plaques was quantified as incremental increase of plaque radii per week (Figure 7d).

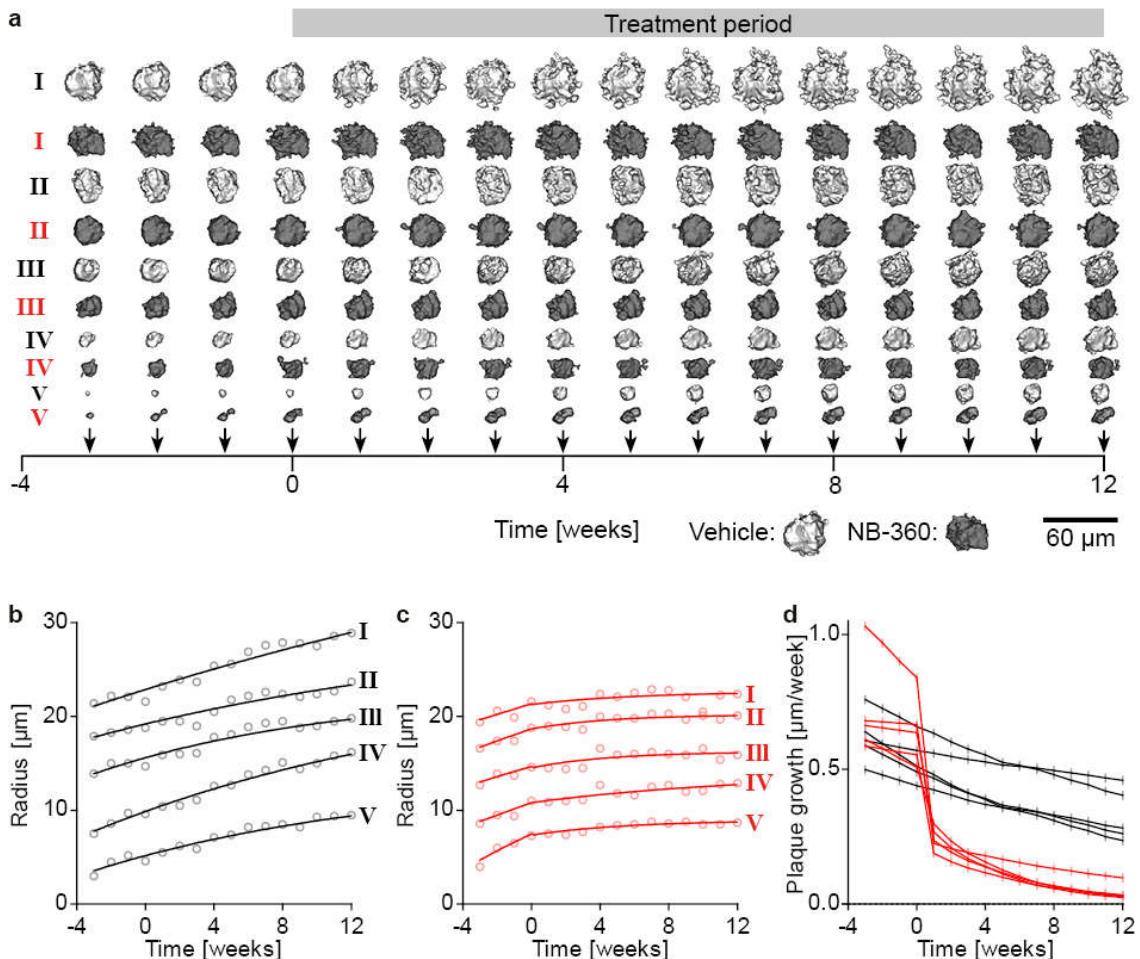

Figure 7. Procedure for determination of plaque growth kinetics. (a) Time series of representative 3D rendered plaques of the vehicle (light gray) and NB-360 (dark gray) treated cohorts. Scale bar represents 60 μ m. (b,c) For the same plaques as in (a) the radii at consecutive time points were calculated, fitted with monophasic association functions, and (d) growth rates at each time point were derived.

The sum of the volume of all plaques per time point was determined and divided by the total imaged brain volume to obtain the overall β -amyloid burden. In vehicle treated mice the β -amyloid burden increases linearly over

2. Results

the total imaging period at a rate of $0.076\% \pm 0.015\%$ brain volume occupied by plaques every week (Figure 8a). Pharmacological BACE1 inhibition significantly slowed down β -amyloid deposition by 49%.

2.4 BACE1 inhibition most effectively lowers formation of new plaques

β -amyloid deposition can occur either by adhesion of soluble A β to the surface of already existing plaques, resulting in plaque growth or via spontaneous aggregation to form new plaques. These two processes follow different kinetics (277) and have distinct biophysical properties (277,280–282). Therefore, it was important to assess whether BACE1 inhibition affects plaque formation and growth to a different degree.

Over the imaging period, plaque growth slightly decreased with time in both cohorts (Figure 8b). Thus, the imaging period relates to the transition phase of β -amyloid deposition (277), when the plaque surface available for further A β accretion, starts to exceed the available levels of soluble A β (277,283–285). Apart from the age-dependent decline, BACE1 inhibition reduced plaque growth rates significantly. Between 1 to 10 weeks mean plaque growth was reduced by approximately 52% (values were normalized to week 0, Figure 8b).

To quantify the plaque formation rate, the density of plaques was determined for each time point (Figure 8c) and gain of plaque density with time was calculated. After 8 weeks of BACE1 inhibitor treatment plaque density was reduced by 18.9% (values were normalized to week 0) compared to vehicle treatment. BACE1 inhibition significantly reduced the formation rate of new plaques (Figure 8d). Mean formation rate was decreased by 12-fold between 4 to 8 weeks after treatment.

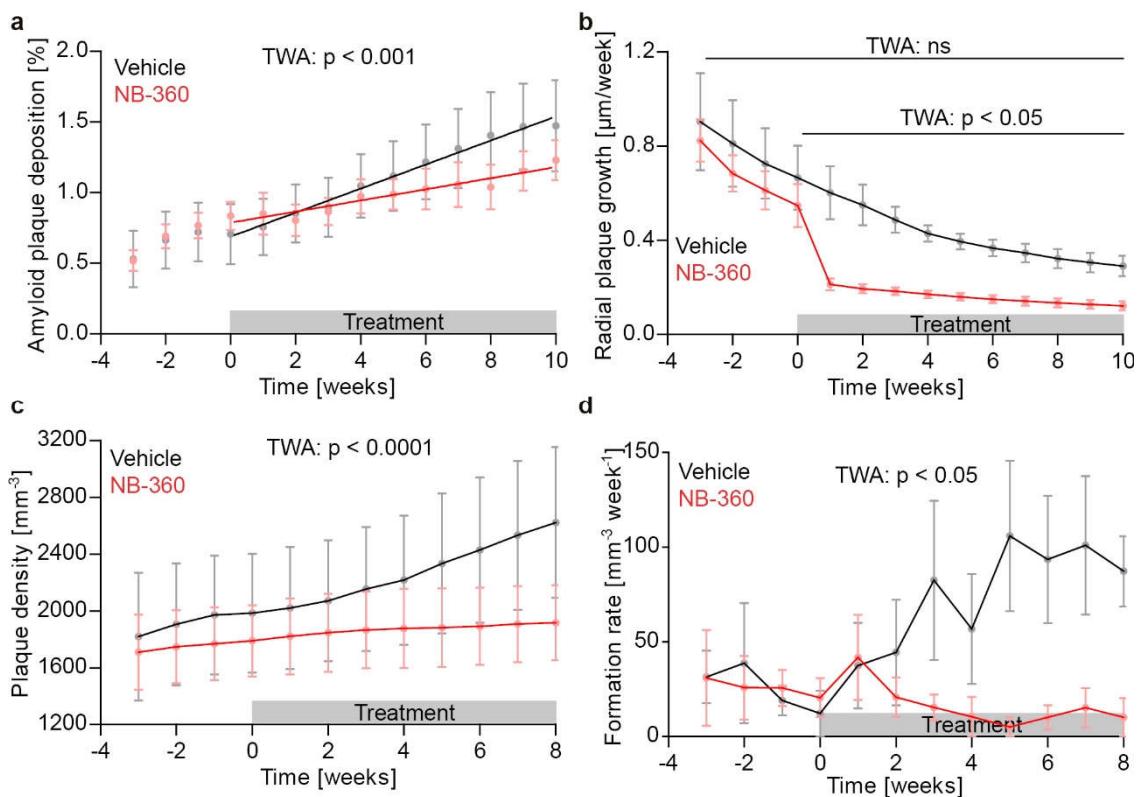

Figure 8. BACE1 inhibition most effectively reduces formation of new plaques. (a) Integrated volume fraction of all β-amyloid plaques (TWA: $F_{int}[13] = 3.31, p < 0.001$; $F_{time}[13] = 35.07, p < 0.0001$). Lines show linear regressions of the data (F-Test, $p < 0.01$). (b) Kinetics of mean plaque growth rates (TWA: $F_{int}[30] = 1.80, p = 0.010$; $F_{time}[10] = 42.90, p < 0.0001$). (c) Kinetics of mean plaque density (TWA: $F_{int}[33] = 4.41, p < 0.0001$; $F_{time}[11] = 35.28, p < 0.0001$), and (d) mean rate of newly formed plaques (TWA: $F_{int}[33] = 1.65, p = 0.020$; $F_{time}[11] = 2.05, p = 0.026$). Data presented as mean ± SEM; $n = 5-6$.

The combined effect of moderately reduced plaque growth and nearly halted plaque formation should also be apparent from the plaque size distribution. For this, plaques were grouped according to their size, and mean plaque densities were obtained. By comparing plaque size distributions before and at 10 weeks after treatment, a general shift to larger plaque sizes could be detected (Figure 9). Most evidently, small plaques only rarely occur after BACE1 inhibition.

2. Results

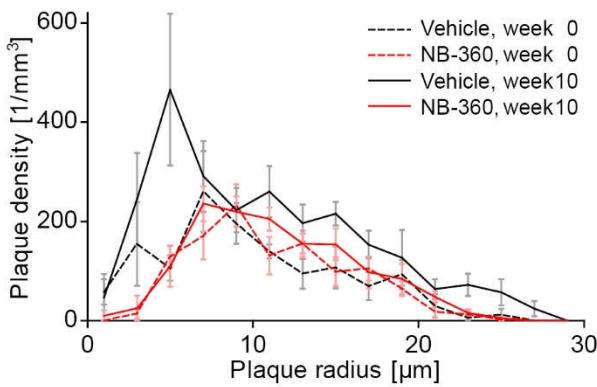

Figure 9. After BACE1 inhibition pre-existing plaques remain smaller and, less small plaques are detected. Frequency distribution of plaque radii at weeks 0 and 10. Reduced plaque formation and growth is reflected in the plaque size distribution as shift to larger radii and lower frequency of small plaque radii. Data presented as mean \pm SEM; $n = 5-6$.

2.5 BACE1 inhibition reduces plaque growth irrespective of plaque size

We further tested whether plaques of different size might be differentially affected by BACE1 inhibition. For this we grouped plaques according to their size and obtained mean growth rates for each time point. BACE1 inhibition reduced plaque growth evenly, irrespective of plaque size (Figure 10a). Thus, once plaques had formed they constantly kept growing and did neither shrink nor disappear throughout the period of BACE1 inhibitor treatment.

The volume that β -amyloid plaques occupy only partly reflects their actual pathological impact. With time microglia and astrocytes are recruited to amyloid plaques which causes secondary detrimental effects in the immediate environment of plaques (286,287). Therefore, in the imaged brain volume we measured the distance of each voxel to the closest plaque (Figure 10b). Before treatment initiation the mean distance to closest plaque was approximately 55 μm and the maximal distance was 160 μm (Figure 10c). BACE1 inhibition

significantly slowed down the reduction in mean distance (Figure 10d) by 48.5% ($-1.03 \pm 0.40 \mu\text{m}/\text{week}$ versus $-0.50 \pm 0.21 \mu\text{m}/\text{week}$), indicating slower β -amyloid deposition.

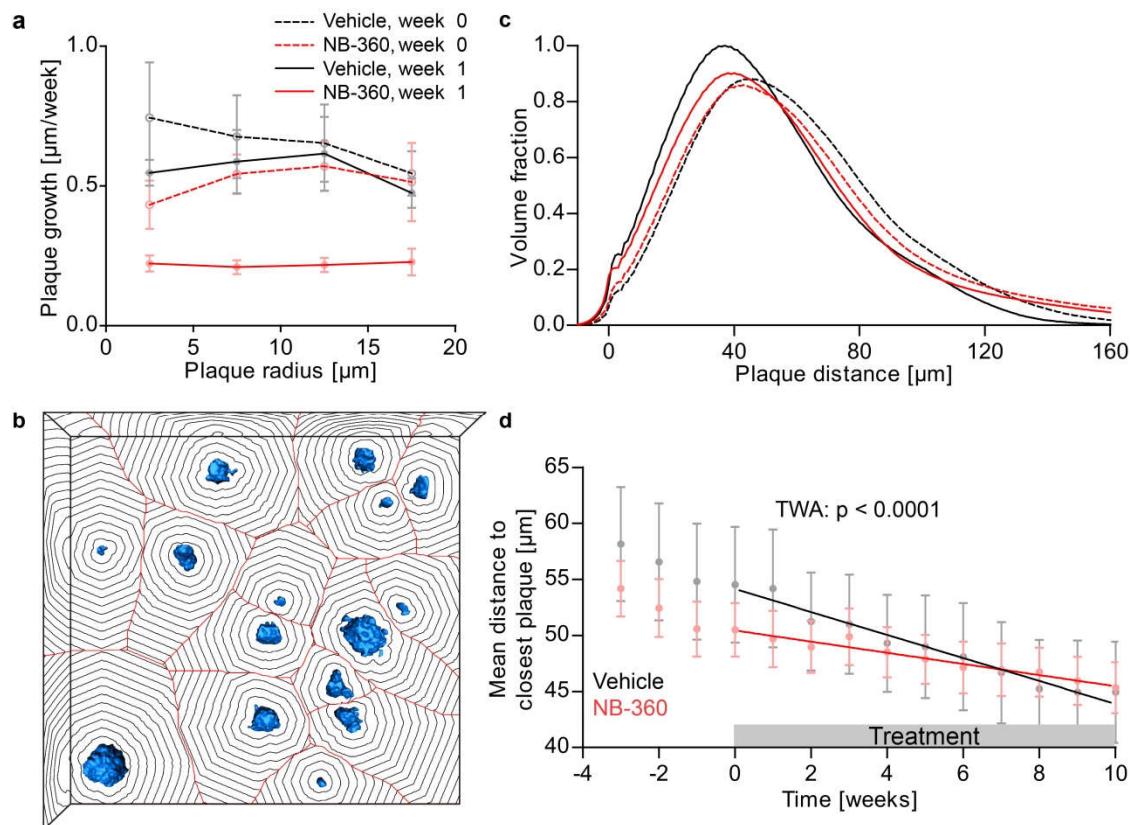

Figure 10. BACE1 inhibition reduces plaque growth independent of plaque size. (a) Growth rates of plaques of different radii before and one week after treatment initiation. (b) In the imaged brain volume the distance of each voxel to the closest plaque was determined via 3D distance transformation. (c) Frequency distribution of the distance of imaged brain volume to the closest plaque surface at weeks 0 and 10. (d) Kinetics of mean distance of brain volume to closest plaque (TWA: $F_{\text{int}}[13] = 3.90$, $p < 0.0001$; $F_{\text{time}}[13] = 41.14$, $p < 0.0001$). Lines show linear regressions of the data (F-Test, $p < 0.05$). Data presented as mean \pm SEM; $n = 5-6$.

2.6 Formation of new plaques is enhanced in vicinity to pre-existing plaques

Previously, it was shown that BACE1 accumulates in peri-plaque dystrophic axons (78,81,193,194). Thus, plaques might locally enhance A β production (76) and thereby further aggravate β -amyloid deposition. To test this hypothesis and to investigate whether inhibition of BACE1 activity might break this vicious pathogenic cycle, we quantified the mean plaque formation rate close and distant to pre-existing plaques within 1 to 8 weeks after treatment start. In vehicle treated mice, the rate of plaque formation within 0-20 μ m distance from pre-existing plaques was 4.2-fold higher as compared to the rate at 80-100 μ m distance (Figure 11a and b). At week 10 shorter inter-plaque distances were significantly more frequent (Figure 11c). In BACE1 inhibitor treated mice, plaque formation was globally reduced, but remained 5.4-fold higher in proximity to plaques.

2.6 Formation of new plaques is enhanced in vicinity to pre-existing plaques

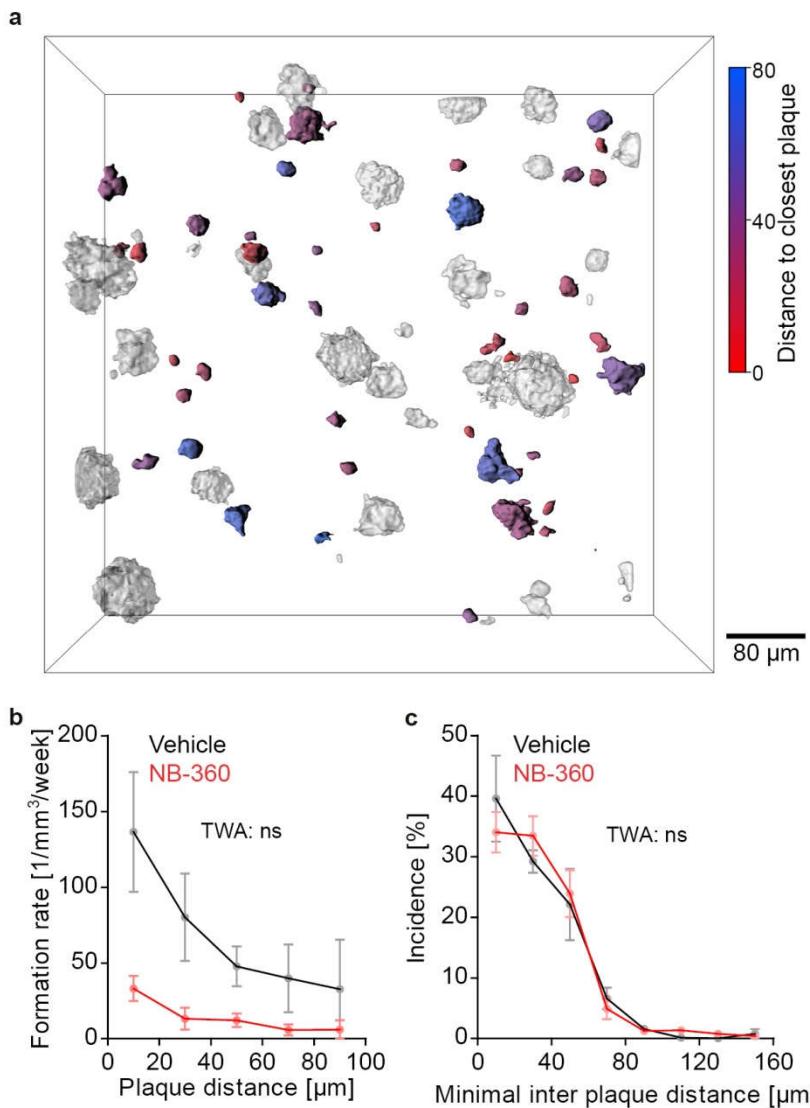

Figure 11. Pre-existing plaques locally enhance further formation of new plaques. (a) Representative image of 3D rendered plaques 10 weeks after treatment. The color map indicates the distance of each newly formed plaque to the closest plaque that was already present when the new plaque formed. White plaques were already present from the beginning. (b) Mean rate of plaque formation after treatment initiation at varying distances to already existing plaques (TWA: $F_{int}[4] = 2.20$, $p = 0.089$; $F_{treatment}[1] = 8.17$, $p = 0.019$; $F_{distance}[4] = 6.17$, $p < 0.001$). (c) Frequency distribution of the minimal distance between each plaque and the closest neighbouring plaque at 10 weeks after treatment (TWA: $F_{int}[7] = 0.46$, $p = 0.863$; $F_{treatment}[1] = 3.27$, $p = 0.104$; $F_{distance}[7] = 52.74$, $p < 0.0001$). Data presented as mean ± SEM; $n = 5-6$.

2.7 BACE1 inhibition fails to prevent BACE1 accumulation in peri-plaque dystrophies

BACE1 distribution was assessed by immunostaining in mice treated for 10 weeks (Figure 12a). Enrichment of BACE1 was detected up to approximately 5 μm from plaque borders (Figure 12b). Local BACE1 accumulation was already evident for small plaques (Figure 12c) and significantly increased with plaque size, reaching a maximum for plaques of 10 μm radius. BACE1 inhibition tended to reduce local accumulation of BACE1 but the effect was not significant (Figure 12c).

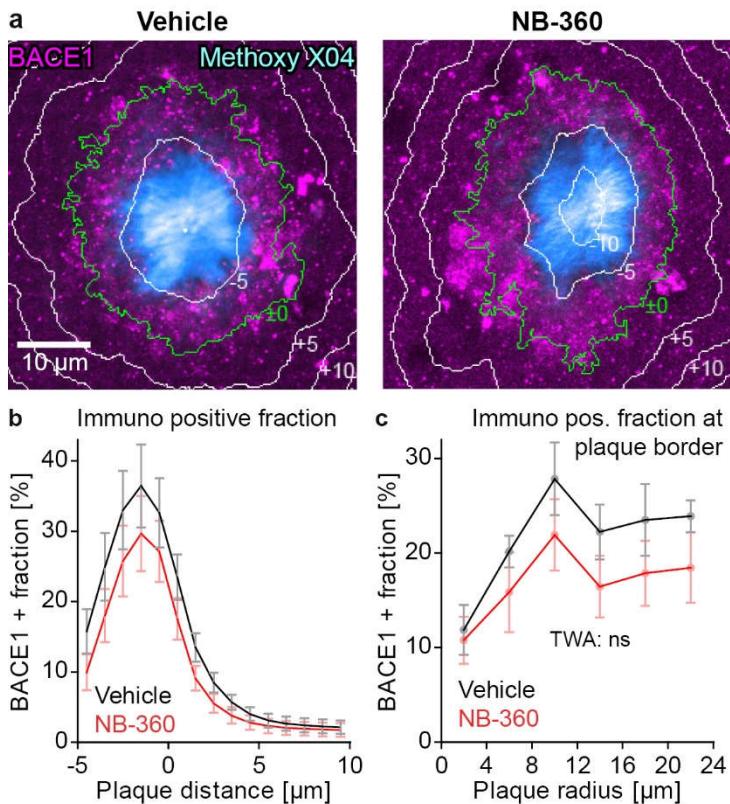

Figure 12. Inhibition of BACE1 activity does not prevent BACE1 accumulation in peri-plaque dystrophies. (a) BACE1 immunostainings 10 weeks after treatment onset. The green line depicts the outer plaque border as defined by Methoxy-X04 fluorescence, and white lines indicate 5 μm spaced distance rings from the plaque border. Scale bar represents 10 μm. (b) Fraction of BACE1 immuno positive brain volume at varying distances to the closest plaque border for plaques of 10-20 μm radius. (c) Mean fraction of BACE1 immuno positive brain volume within 1 μm distance from plaque border for plaques of increasing radii (TWA: $F_{int}[15] = 0.20, p = 1.000; F_{treatment}[3] = 1.33, p = 0.294; F_{radius}[5] = 14.04, p < 0.0001$). Data presented as mean ± SEM; $n = 5-6$.

2.8 BACE1 inhibition mitigates progression of presynaptic pathology

The question arose whether the beneficial impact of BACE1 inhibition on β-amyloid deposition would mitigate synaptic pathology. The VGLUT1^{Venus} fluorescence pattern appeared punctate with small sphere-like presynaptic

2. Results

boutons distant from plaques and large swollen axonal dystrophies in proximity to plaques (Figure 13a). Custom-written Matlab cluster analysis was applied for automated morphological segmentation. VGLUT1-positive structures became larger with increasing plaque size and developed within a range of up to 5-10 μm around plaque borders (Figure 13b).

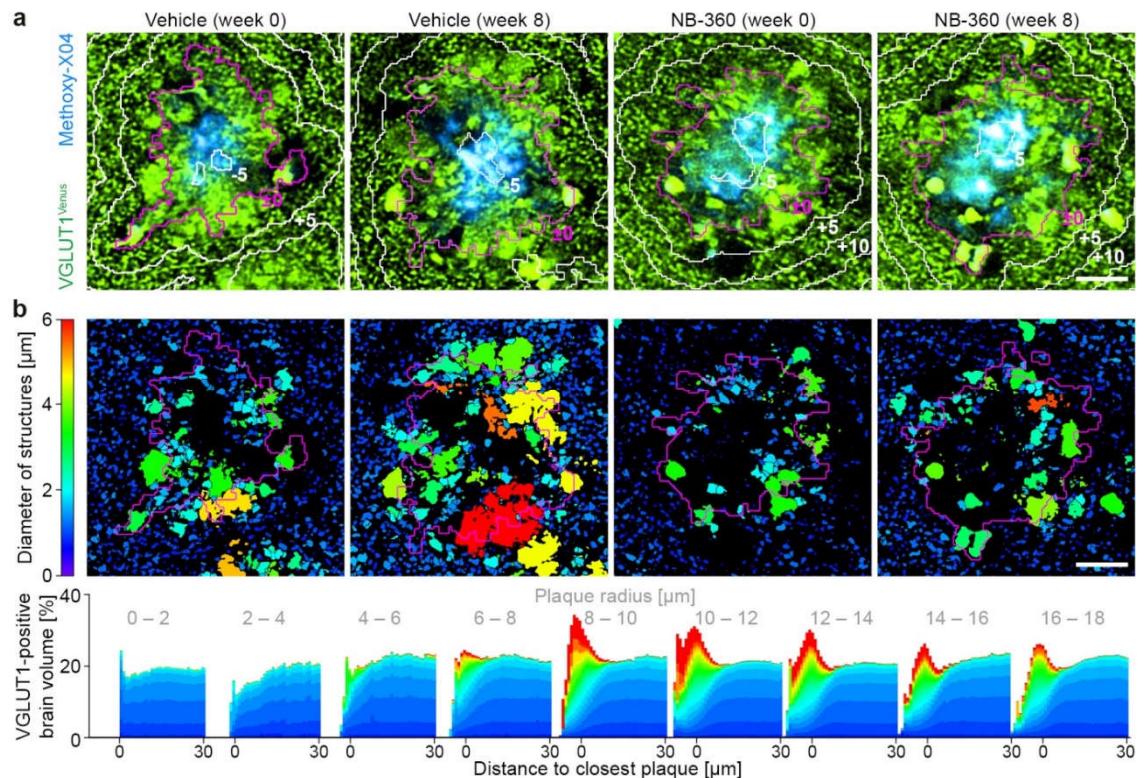

Figure 13. BACE1 inhibition mitigates progressive axonal pathology. (a) VGLUT1^{Venus} fluorescence micrographs for two plaques before and 8 weeks after treatment. (b) Segmentations of the respective images in (A), with color code indicating the minimal diameter of individual VGLUT1-positive structures. Magenta colored lines depict the outer plaque border and white lines indicate 5 μm spaced distance rings from plaque border. The cumulative distributions (below) indicate the proportion change of differently sized VGLUT1-positive structures with distance to closest plaque. Data presented as mean \pm SEM.

A previous publication reported that axons with severe plaque-associated dystrophies can develop secondary dystrophies even distant to plaques (288). Consistently, in 6 months old APPPS1xVGLUT1^{Venus} mice, large VGLUT1-positive structures emerged more frequently even distant ($>30 \mu\text{m}$) from

plaques as compared to wild type VGLUT1^{Venus} mice of same age (Figure 14a). BACE1 inhibition had no evident impact on that specific pathology. According to their diameter, VGLUT1^{Venus}-positive structures were classified either as boutons or axonal dystrophies. A diameter of 2.0 μm was defined as maximal threshold for boutons, since in wild type mice less than 1.0% of VGLUT1-positive structures were larger. Furthermore, a diameter of 2.0 μm also demarcated the transition size, at which VGLUT1-positive structures became more abundant in proximity to plaques (Figure 14b). In proximity to plaques the fraction of brain volume occupied by axonal dystrophies depended on plaque size. The corona of axonal dystrophies became denser with increasing plaque radius and was maximal for plaques of 10 μm radius (Figure 14c). BACE1 inhibition tended to reduce the extent of axonal dystrophies at the plaque border, but this effect did not reach statistical significance. However, with time the total amount of plaque-associated axonal dystrophies increased at a 10-fold reduced rate in BACE1 inhibitor treated mice. (Figure 14d).

2. Results

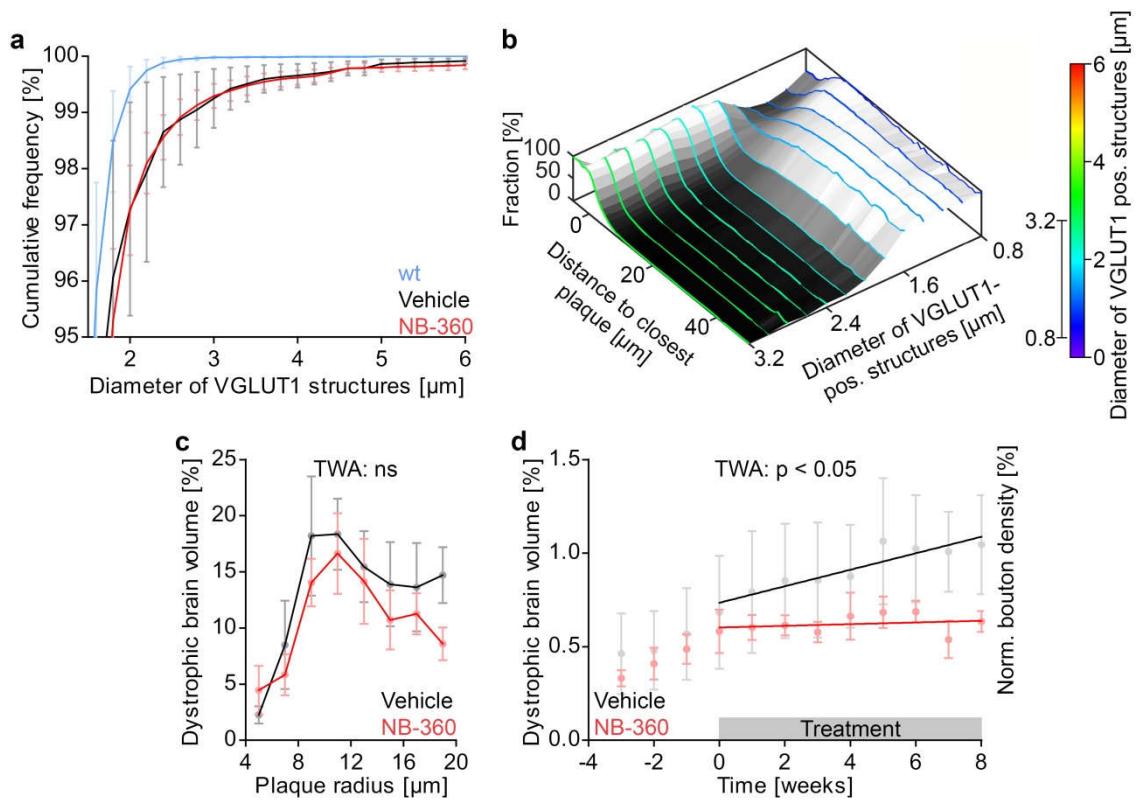

Figure 14. BACE1 inhibition mitigates progression of presynaptic dystrophies. (a) Cumulative distribution of VGLUT1-positive brain volume according to the diameter of VGLUT1-positive structures distant ($>30 \mu\text{m}$) from plaques after 8 weeks of treatment. Age-matched, untreated VGLUT1^{Venus} mice were used as control. (b) Normalized distribution of VGLUT1-positive structures of distinct size. Only structures with minimal diameter from 0.8 to 3.2 μm are shown in order to highlight the transition range. Small structures up to 1.8 μm diameter are abundant distant to plaques. Structures of 2.0 μm diameter or higher are abundant in proximity but are reduced distant to plaques ($n = 10$ mice, before treatment onset). (c) Fraction of brain volume within 1 μm distance from plaque border occupied by axonal dystrophies (TWA: $F_{\text{int}}[7] = 0.43$, $p = 0.882$; $F_{\text{treatment}}[1] = 0.94$, $p = 0.360$; $F_{\text{radius}}[7] = 6.46$, $p < 0.0001$). (d) Total fraction of dystrophic brain volume within 10 μm distance from plaque border (TWA: $F_{\text{int}}[11] = 2.29$, $p = 0.016$; $F_{\text{time}}[11] = 12.60$, $p < 0.0001$). Lines show linear regressions of the data (F-Test, ns). Data presented as mean \pm SEM; $n = 4$ vehicle, $n = 6$ NB-360 and $n = 3$ control mice.

2.9 BACE1 inhibition fails to prevent plaque associated bouton loss

The density of boutons locally decreased in proximity to plaques (Figure 15a). This bouton loss became more pronounced with increasing plaque radius, but did not differ between treatment cohorts (Figure 15b). No significant change in bouton density between cohorts was observed over time (Figure 15c).

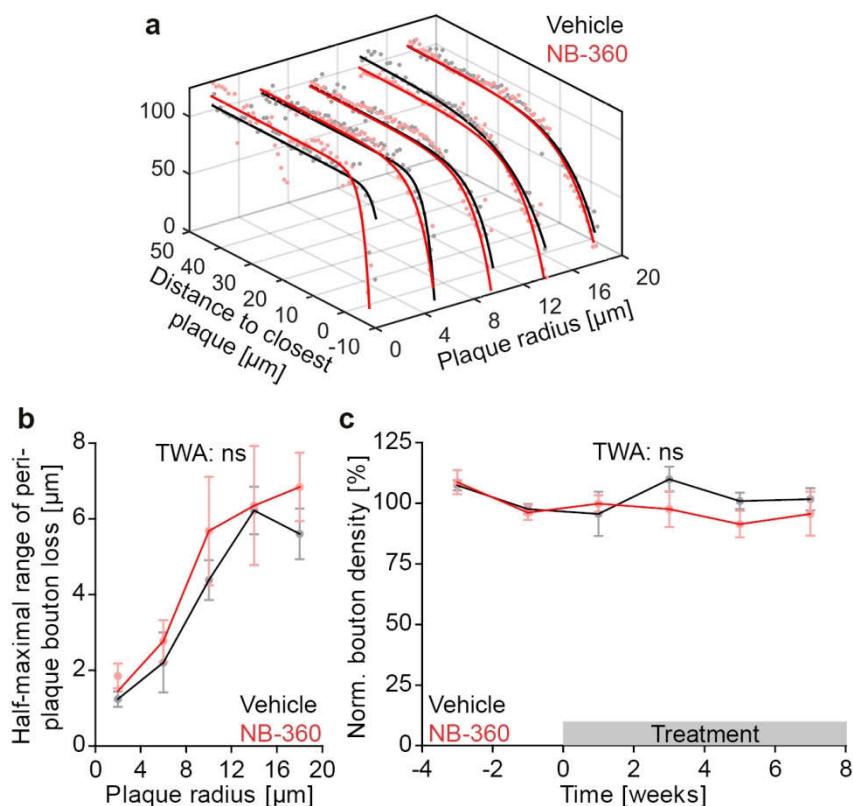

Figure 15. BACE1 inhibition does not prevent plaque-associated bouton loss. (a) Quantification of the densities of VGLUT1-positive boutons after treatment onset at varying distances and for plaques of varying radii. Traces were fitted with monophasic association functions to obtain the half-distance. (b) Toxic effect of plaques of increasing radii on bouton density, measured as the half-distance of monophasic association fits (TWA: $F_{int}[4] = 0.13$, $p = 0.972$; $F_{treatment}[1] = 1.22$, $p = 0.302$; $F_{radius}[4] = 9.93$, $p < 0.0001$). (c) Global bouton densities normalized to time points before treatment ($F_{int}[6] = 0.76$, $p = 0.605$; $F_{time}[6] = 1.95$, $p < 0.0921$). Data presented as mean \pm SEM; $n = 4-6$.

3. Discussion

According to the prevailing theory, the amyloid cascade hypothesis, the initial cause for AD is the cerebral accumulation and aggregation of A β . Due to the synaptotoxic effect of these A β aggregates, synapses are lost and nerve cells degenerate which manifests in progressive cognitive decline (98,289). Based on this hypothesis, in the current study the impact of the A β lowering BACE1 inhibitor NB-360 was tested in a transgenic mouse model of AD.

3.1 Amyloid plaque kinetics

At the provided dosage BACE1 inhibitor treatment reduced soluble A β levels in APPS1 mice by 5-fold, plaque growth by 2-fold, and plaque formation by 12-fold. The particularly strong impact of the treatment on the formation of new plaques might have two mechanisms.

- i. Nucleation seed formation requires a higher critical A β concentration than accretion to already existing β -amyloid fibrils (277,280–282). Thus, reduction of A β level decreases the likelihood of new plaque formation more strongly than plaque growth.
- ii. Accumulation of BACE1 in peri-plaque dystrophies (78,81,193,194) might enhance local A β generation (76). Indeed, our observation of increased plaque formation close to existing plaques, support the notion that A β generation is elevated in vicinity of plaques. Additionally, even though BACE1 inhibition effectively reduces BACE1 activity the treatment does not rescue abnormal accumulation of BACE1 in peri-plaque dystrophies.

Therefore, once a plaque has formed, excessive BACE1 accumulation amplifies local A β generation even when BACE1 activity is inhibited.

Thus, at a stage when β -amyloid pathology has commenced, these mechanisms aggravate pharmacological intervention to block further A β deposition. Consistently, BACE1 inhibition only moderately reduces growth of pre-existing plaques, while plaque formation is almost halted in APPPS1 mice.

3.2 Synaptic A β pathology

BACE1 inhibitor treatment reduced the rate of presynaptic dystrophy formation by 10-fold, which indicates a beneficial impact on synaptic toxicity. However, the total density of presynaptic boutons did not significantly differ between treatment cohorts. There are two possible explanations for this discrepancy. In APPPS1 mice bouton loss is restricted to the proximity of plaques and – depending on plaque size – returns to normal density within 5 to 10 μm from plaque border. The BACE1 inhibitor treatment results in 0.5 % reduced β -amyloid deposition compared to vehicle treated APPPS1 mice. For detection of such small changes, the variability of bouton density in different mice is too high. Another explanation would be that the beneficial local impact of the treatment on plaque-associated synaptic pathology is balanced by adverse effects of BACE1 inhibition on synapse density (179,180).

3.3 BACE1 inhibitor dosage

In light of dose-dependent adverse effects of BACE1 inhibition in mice (179,180,290), it is critical to minimize BACE1 inhibitor dosage as much as possible. This particularly applies for preventive treatment that will require life-

3. Discussion

long drug administration, starting at an age when patients are still healthy and accurate prediction of AD might not always be ensured.

Inhibition of BACE1 seems to be clinically beneficial in the context of elevated BACE1 and A β levels in brains of AD patients (195,196,200). However, the unequal distribution of BACE1 poses a major obstacle for pharmacological BACE1 inhibition. An adequate BACE1 inhibitor dosage, necessary to sufficiently inhibit the high BACE1 levels in peri-plaque axonal dystrophies (78,81,193,194), might cause excessive inhibition of physiological BACE1 activity distant to plaques. Conversely, partial BACE1 inhibition to ensure physiological BACE1 activity might prevent potential mechanism-based adverse effects (179,180,290), but might not suffice to break the vicious cycle of self-sustained A β generation close to plaques.

The finding of utmost susceptibility of plaque formation in response to BACE1 inhibition, points to a therapeutical strategy that might balance potential adverse effects and sufficiently efficacious reduction of β -amyloid deposition. Such a compromise would be to aim for a BACE1 inhibitor dosage that prevents formation of new plaques rather than aiming for complete arrest of plaque growth. This strategy would be directed at delaying rather than halting the progression of AD at any rate.

Since in human patients A β levels are generally lower as compared to APPPS1 mice, it is important to remark that it is possible that a narrow range of BACE1 inhibition dosage exists that is tolerable and still completely halts β -amyloid deposition. However, given the adverse effects in mice this might not be an optimal primary clinical endpoint.

Furthermore, enhanced plaque formation rate in the vicinity of pre-existing plaques might be causative for the characteristic spreading of β -amyloid

deposition that typically initiates locally and then gradually disperses into adjoining unaffected brain regions (28–33). This conclusion is in agreement with previous studies, reporting that plaque deposition gradually invades grafted wt tissue in AD mice (291,292). Thus, even if halting plaque growth in humans might turn out to be difficult, it could suffice to abort plaque formation by BACE1 inhibition and thereby prevent further spreading into neighbouring brain regions. For translation of this pharmacological strategy into clinical therapy, it would be necessary to empirically determine the range of BACE1 inhibitor dosage that effectively halts the spreading of β -amyloid deposition into unaffected brain regions, e.g. by PET imaging.

3.4 Timing of pharmacological BACE1 inhibition

The formation of new plaques typically occurs in the initial stage of β -amyloid progression and ultimately reaches a plateau of maximum density (31). In addition, experimental data from mice indicate that towards later stages new plaques rarely form while existing plaques continue to grow (277,279).

In this study only a single dosage was tested at one stage of β -amyloid pathology. However, the key finding of differential impact on plaque formation and growth allows some logical assumptions on the potential outcomes of BACE1 inhibitor treatment applied at different dosages and at different stages of β -amyloid progression (illustrated in Figure 16):

1. For primary prevention treatment, before A β accumulation, low BACE1 inhibitor dosage might suffice to restrict A β levels below the critical concentration that is required for plaque-seeding. In agreement with this notion, life-long reduction of A β levels by 40% results in 5- to 7-fold reduced risk of developing AD (146). Additionally, a slight reduction of A β levels by

3. Discussion

12% due to heterozygous expression of BACE1 reduces total A β deposition by 50% in aged *Bace1*^{+/-} mice (256). Moreover, prophylactic therapy with a γ -secretase inhibitor results in sustained reduction of amyloid plaque pathology in Tg2576 mice (293). The current work and a previous publication (294) indicate, that plaque formation is locally enhanced at plaques and limited up to approximately 50 μ m distance from pre-existing plaques. Thus, as long as β -amyloid deposition is still locally confined in the brain, the strategy of halting plaque formation with low BACE1 inhibitor dosage could still apply to suppress further spreading of β -amyloid pathology into yet unaffected parts of the brain.

2. Secondary prevention treatment applies, when substantial parts of the brain are already affected with initial β -amyloid deposition. Under these conditions, β -amyloid deposition might even continue at A β levels below the critical concentration for nucleation seed formation. In addition, BACE1 inhibition therapy has to compensate for increased A β generation close to plaques. In APPPS1 mice BACE1 inhibitor treatment nearly halts plaque formation and effectively slows down β -amyloid deposition with no sign of compensatory adaptation to the inhibitor over the 2.5 months long treatment period. Even more importantly, the treatment also slows down the progression of plaque-related axonal pathology. While these results imply that β -amyloid pathology can at least be delayed, previous end point studies in other murine AD models indicate that β -amyloid deposition might even be halted completely (233,234).
3. Late-stage treatment in the saturation phase of β -amyloid deposition, might not be sufficient to stop disease progression. Our longitudinal *in vivo* approach shows that in APPPS1 mice, BACE1 inhibition failed to clear plaques that were already present at treatment initiation, and even though

the progression of axonal pathology was slowed down it could not be reverted. This might also explain the recently reported failure of the BACE1 inhibitor verubestat in one clinical late-stage trial for the treatment of AD.

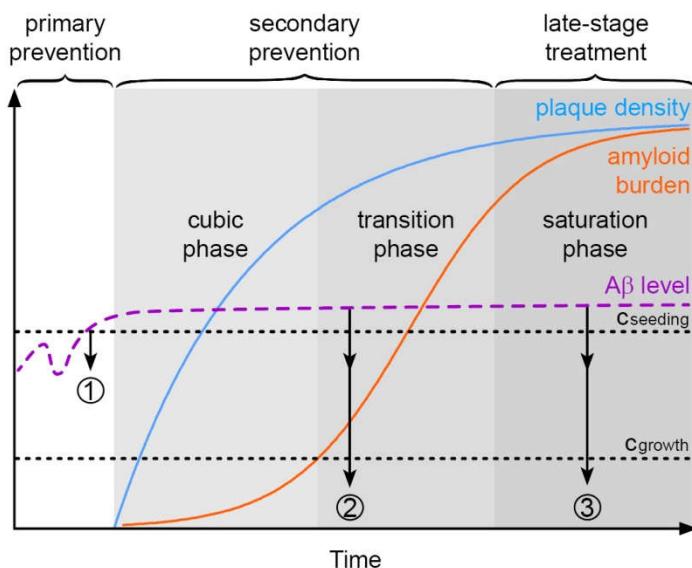

Figure 16. Hypothetical model on the impact of different therapeutic BACE1 inhibitor approaches on the kinetics of amyloid deposition. The dashed magenta line delineates speculative A β levels. Before initial plaque deposition A β levels might transiently and locally surpass the critical concentration for plaque formation. Once formed, plaques exacerbate local A β -levels via BACE1 accumulation. ① Low BACE1 inhibitor dosage starting already before initial amyloid deposition suffices to suppress A β levels constantly below the critical concentration for plaque seeding (c_{seed}). ② After plaque deposition has commenced moderate BACE1 inhibitor doses are required to suppress A β levels below c_{seed} and suppressing plaque growth might only be achievable with high and probably toxic BACE1 inhibitor dosing. ③ In the saturation phase, plaque deposition reaches a plateau with little space for beneficial influence of any BACE1 inhibitor dosage.

3.5 Conclusion

Altogether, the data imply that BACE1 inhibition is most effective if given as early as possible in the progression of β -amyloid pathology. Predictive genetic testing for familial AD would allow to initiate treatment already prophylactically.

3. Discussion

However, the majority of AD patients lack predictive genetic markers and β -amyloid deposition is among the earliest pathological alterations in the AD brain (1). Thus, for the majority of AD patients presymptomatic diagnosis will even in future be limited to a stage when first plaques have already formed. Therefore, in this study the effect of BACE1 inhibitor treatment was tested at a stage, when β -amyloid deposition has already commenced but has not yet saturated, as can be deduced from the linear slope of β -amyloid deposition.

The major future challenge will be to identify early AD biomarkers. Indeed, clinical biomarkers have already been determined that enable AD diagnosis several years before symptom onset (1,295), thus paving the way for presymptomatic treatment.

To take advantage of the particular inhibitor susceptibility of plaque formation, treatment should be commenced when β -amyloid deposition is still locally confined in the brain. Thus, a moderate dosage of BACE1 inhibition might suffice to halt or at least delay the progression of β -amyloid pathology to AD. This treatment strategy would ensure moderate suppression of physiological BACE1 function (296) and thus reduces the risk of potential mechanism-based adverse effects (179).

Apart from inhibiting BACE1 activity another therapeutical approach might be to target accumulation of BACE1 at plaques or alleviate the formation of axonal dystrophies. For this, it will be indispensable to understand the pathological mechanisms that cause axonal swelling and subsequent accumulation of BACE1. One possible mechanism has been brought up recently, in which A β causes microtubule disruption and motor protein mis-localization (76,77). As a result retrograde transport and thereby maturation of lysosomes is impaired (201,202) which causes BACE1 and other proteins to accumulate in peri-plaque dystrophic neurites (76,77). It would be highly relevant to identify a

target within this cascade to interfere with axonal dystrophy formation and thereby BACE1 accumulation. A recent study has shown that swollen axonal varicosities are highly dynamic with strong changes of volume within weeks (297). Consequently, the emergence of peri-plaque axonal dystrophies seems to be reversible within a certain time window. A strategy that would alleviate axonal pathology at plaques in combination with tolerable BACE1 inhibitor dosage might represent an effective future therapeutic approach to interfere with β -amyloid progression.

4. Materials and Methods

4.1 BACE1 inhibitor

NB-360 was synthesized and kindly provided by Novartis. The pharmacologic properties have been characterized previously by Neumann and colleagues (233). Mice were fed *ad libitum* with food pellets containing NB-360 (0.25 g/kg) or control pellet.

4.2 Transgenic mice

All protocols and procedures involving animals were approved and conducted in accordance with the regulations of the Ludwig-Maximilian University and the Government of Upper Bavaria (Aktenzeichen 55.2-1-54-2532-62-12). Heterozygous APPPS1 mice co-express a human APP with the Swedish mutation (KM670/671NL) and a mutated PS1 (L166P) under the neuron-specific Thy1-promoter (89). APPPS1 mice were crossbred with homozygous VGLUT1^{Venus} knock-in mice that express the Vesicular GLUtamate Transporter 1, fused to the fluorescent protein Venus under the endogenous VGLUT1 promoter (90). Non-transgenic APPPS1^{-/-} littermates crossed with homozygous VGLUT1^{Venus} mice served as control. Mice were of both sexes and group-housed under pathogen-free conditions until surgery, after which they were single-housed.

4.3 Statistical Analysis

For statistical analysis, GraphPad Prism 5 (GraphPad Software, San Diego, California) was used. Data were tested for normality using D'Agostino-Pearson omnibus K2 test and Kolmogorov-Smirnov test. Intergroup comparisons were performed using two-tailed unpaired Student's *t*-test. In the longitudinal measurements variables were compared across groups using two-way ANOVA (TWA) and *p* values refer to the test of interaction unless further specified. When treatment effects, genotype effects, time effects, interactions were found, post-hoc analyses were performed using Bonferroni analysis. All results are presented as mean ± SEM unless further specified.

4.4 Plasma and brain homogenization and extraction

Mice were deeply anesthetized with an intraperitoneal injection of ketamine and xylazine (130/10 mg/kg respectively). Blood was collected via cardiac puncture into EDTA tubes (BD microtainer tubes with K2EDTA #365974) on wet ice and was centrifuged at 1500 g for 15min at 4°C. Plasma was obtained from the supernatant and was frozen at -80°C. Brains were isolated, quick-frozen on dry ice and stored at -80°C. Frozen murine forebrains were homogenized in 9 volumes of ice-cold Tris-buffered saline (pH 7.4) containing Complete protease inhibitor cocktail (Roche Diagnostics, Penzberg, Germany) using a Sonifier 450 (Branson) and stored in aliquots at -80°C. Triton X-100 soluble Aβ was extracted by mixing 50 µl 2% Triton X-100 with 50 µl homogenate, incubating for 15 minutes on ice with vortexing, followed by ultracentrifugation at 100000 x g for 15 minutes. The clear supernatant was diluted to a final forebrain dilution of 1:100 and used for analysis.

4.5 A β quantification

Six weeks old APPPS1 mice were treated for 2 weeks with vehicle or NB-360-dotted food pellets and were sacrificed subsequently to collect blood and brain samples. A β 40 and 42 were determined in the forebrain and plasma using the electro-chemiluminescence immuno assay kits based on 6E10 from Meso Scale Discovery (Rockville, MD, USA) in either singlet or triplet format. Samples and standards were prepared according to the manufacturers protocols.

4.6 Cranial window implantation

A cranial window was implanted over the right cortical hemisphere as previously reported (298,299). To minimize risk of postoperative wound infection, surgical tools were thermically sterilized with a table top steriliser (Fine Science Tools, Heidelberg, Germany). The surgery was performed with a SZ51 stereo microscope (Olympus, Hamburg, Germany) and a KL 1500 LED cold light Schwanenhals lamp (Schott, Mainz, Germany). Mice were anesthetized with an intraperitoneal injection of ketamine/xylazine (130 mg/kg ketamine and 10 mg/kg xylazine in 0,9% NaCl). Anesthesia depth was surveilled by testing the interdigital reflex. After adequate anesthesia was achieved, dexamethason was intraperitoneally administered (6 mg/kg in 0,9% NaCl) as anti-inflammatory to prevent the development of cerebral oedema during trepanation of the skull. Additionally, to circumvent postoperative pain and inflammation, the mice were administered a subcutaneous injection of the analgesic carprophen (7,5 mg/kg in 0,9% NaCl) and the antibiotic cefotaxim (250 mg/kg in 0,9% NaCl). Subsequently, mice were placed on a heating plate (Fine Science Tools, Heidelberg, Germany) to keep body temperature during

the surgery constant at 37°C. The mouse head was fixated with a MA-6N holder (Narishige, Tokyo, Japan) and the eyes were protected from dehydration by applying bepanthene ointment. Fur of the skull was disinfected with 70% ethanol and the scalp was removed with a scissor, without damaging the temple muscle. Loose hair at the wound margin was removed with a sterile cotton swab and the periosteum was removed with a scalpel. To reinforce adhesion of dental cement to the skull, a thin layer of Cyano-Veneer liquid glue (Hager und Werken, Duisburg, Germany) was applied on the wound margin and the exposed skull. Subsequently, a circular trepanation of the skull of 5 mm diameter was applied with a C1-Master dental drill (Schick Dental, Schemmerhofen, Germany) above the somatosensory cortex (stereotactic coordinates relative to Bregma: 2 mm caudal und 2,5 mm lateral). Particles of bone were removed with an electric vacuum pump. A drop of PBS was put on the craniotomy to prevent that the cortex dries after opening of the skull. Then the bone was carefully lifted with curved forceps. Slight bleedings were staunched by rinsing with PBS and application of hemostatic gelfoam (Pfizer, New York, USA). Subsequently, a round coverslip of 5 mm diameter (Fine Science Tools, Heidelberg, Germany) was implanted above the craniotomy and PBS was removed with sterile Sugi absorbent swabs (Kettenbach, Eschenburg, Germany). The gap between cover slip and margin of the skull was sealed with histoacryl tissue adhesive (B. Braun Melsungen AG, Melsungen, Germany) and the skull was covered with dental cement (Cyano-Veneer; Hager Werken, Duisburg, Germany). To allow repositioning of the mouse during subsequent imaging sessions a metal bar was attached to the skull and was fixated with dental cement. Until the moment of awakening the animal was placed on a heating pad and was subsequently transferred back to the home cage.

4. Materials and Methods

Table 1. Materials for cranial window implantation.

| <i>Product</i> | <i>Manufacturer</i> |
|--|------------------------------------|
| Ketamine 10 % | WDT, Garbsen |
| Xylazine | Bayer HealthCare, Leverkusen |
| Dexamethasone | Sigma-Aldrich, Taufkirchen |
| Rimadyl (active agent Carprofen) | Pfizer, Berlin |
| Cefotaxim | Pharmore, Ibbenbüren |
| Isoflurane (Forene) | Abbott, Wiesbaden |
| Inhalation anaesthetic set Trajan808 | Dräger Medical, Lübeck |
| Gas mask for mice | Custom-made |
| Heating plate fore mice | FST, Heidelberg |
| Mouse holder for surgery | Custom-made |
| Bepanthene | Bayer HealthCare, Leverkusen |
| Stereo microscope SZ51 | Olympus, Hamburg |
| Table top sterilizer FST 250 Hot Bead Sterilizer | FST, Heidelberg |
| Drill C1 Master | Schick Dentalgeräte, Schemmerhofen |
| Drill head | Gebrüder Brasseler, Lemgo |
| Vacuum suction device | Custom-made |
| Syringe 1ml | VWR, Ismaning |
| Cannula 27G/20G | VWR, Ismaning |
| Ethanol (70%) | Sigma-Aldrich, Taufkirchen |
| Surgical tools (scissors & forceps) | FST, Heidelberg |
| Scalpel | Swann-Morton, Sheffield, UK |
| Cotton swab, sterile | Paul Böttger, Bodenmais |
| Hemostatic gelfoam | Pfizer, Berlin |
| Absorbent swabs Sugi, sterile | Kettenbach, Eschenburg |
| Cover slips (5 mm diameter) | Gerhard Menzel, Braunschweig |
| Dental adhesive Cyano-Veneer Starter Kit | Hager & Werken, Duisburg |
| Titanium-bar | Custom-made |

4.7 Immunohistochemistry

Deeply anesthetized mice (130/10 mg/kg b.w. ketamine/xylazine i.p. WDT/Bayer Health Care) were perfused with phosphate-buffered saline (PBS) followed by 4% formalin solution. Mouse brains were dissected and post-fixed in 4% formalin for 24 hours. Fixed brains were cut into coronal 50 µm thick sections on a vibratome (VT1000S, Leica). Brain slices were permeabilized for 2 hours with 1% Triton X-100 and 10% normal goat serum (Sigma-Aldrich) in PBS. Slices were then incubated with rabbit polyclonal antibody directed against BACE1 (1:1000; BAce-Cat1) (194) in 0.5 % Triton X-100 for 2 days at 4 °C. Sections were washed in PBS and incubated with the secondary antibody coupled to Alexa633 (anti-rabbit 1/500, Invitrogen) 2 h at RT. To detect amyloid fibrils slices were incubated for 15 min with 10 µg/mL Methoxy-X04 in 50% ethanol and washed three times with 50% ethanol at RT. Sections were finally washed for 5 times 10 min with PBS before mounting them on glass coverslips with fluorescence conserving media (Dako).

4.8 Microscopy

4.8.1 Confocal microscopy

Images were acquired with an inverse LSM 780 confocal microscope (Zeiss) equipped with a 40x/1.4 oil immersion objective. Excitation wavelengths were 405 and 561 nm, emission was collected at 410–580 nm for Methoxy-X04 and 585–735 nm for BACE1. In each mouse brain 3-dimensional 16 bit data stacks of 1024 x 1024 x 100 pixels were acquired from 20 different positions in the somatosensory cortex at a lateral resolution of 0.1 µm/pixel and an axial resolution of 0.2 µm/pixel.

4.8.2 Chronic two-photon *in vivo* imaging

In vivo two-photon imaging was started after a recovery period of 3-4 weeks. For amyloid staining Methoxy-X04 (301) was intraperitoneally injected 24 h before imaging at a dose of 0.5 mg/kg body weight. Throughout the imaging sessions, mice were anesthetized with isoflurane (1% in 95% O², 5% CO², Forene®, Abbott), placed on a heating pad to keep body temperature at 37°C (Fine Science Tools GmbH) and fixed to a custom-made holder using the glued metal plate. *In vivo* two-photon imaging was performed on a LSM 7 MP (Carl Zeiss) equipped with standard photomultiplier detectors and a 20x water-immersion objective (W Plan-Apochromat 20x/1.0 DIC, 1.0 NA, Carl Zeiss). For each mouse, one region of interest was reimaged at a weekly interval. In each imaging session two data stacks were obtained consecutively. To resolve the presynaptic boutons, a high-resolution 3D stack was obtained from the VGLUT1^{Venus} fluorescence in cortical layer I at a resolution of 0.08x0.08x0.4 μm³ and dimensions of 283x283x60 μm³. Subsequently a larger but less resolved 3D stack was obtained from the Methoxy-X04 fluorescence at a resolution of 0.24x0.24x0.4 μm³ and dimensions of 425x425x200 μm³. Methoxy-X04 was excited at 750 nm by a Ti:Sa laser (MaiTai DeepSee, Spectra-Physics) and emission was collected below 485 nm. VGLUT^{Venus} was excited at 915 nm and emission was collected from 470 to 550 nm. For both stacks the autofluorescence was recorded simultaneously at an emission range from 590 to 650 nm. In subsequent imaging sessions, the previously imaged volumes were identified by eye using the unique blood vessel pattern. This allowed a precise alignment of the same imaging volumes. The laser intensity was adjusted to keep the emitted fluorescence stable at different depths using the z-correction tool in the microscope control software and also at subsequent

imaging sessions. All images were of optimal quality and did not suffer from motion artefacts due to breathing or heart beating of the animal.

Table 2. Imaging settings for acquisition of Methoxy-X04 and VGLUT1^{Venus} fluorescence.

| | <i>Methoxy-X04</i> | <i>VGLUT1 Venus</i> |
|-----------------------|----------------------------|----------------------------|
| Excitation wavelength | 750 nm | 915 nm |
| Pixel size | 1800 x 1800 x 501 | 3600 x 3600 x 151 |
| Image size | 425 µm x 425 µm x 200 µm | 283 µm x 283 µm x 60 µm |
| Resolution | 0.24 µm x 0.24 µm x 0.4 µm | 0.08 µm x 0.08 µm x 0.4 µm |
| Pixel dwell time | 0.45 µs (no average) | 0.45 µs (average 2x) |
| Emission channels | SP 485 & BP 590-650 | SP BP470-550 & BP 590-650 |

4.9 Data analysis of 3D microscopical data

All data stacks obtained by *in vivo* two-photon microscopy were deconvoluted using AutoQuant (AutoQuantX3, Media Cybernetics). For quantification amyloid plaques, presynaptic boutons, presynaptic dystrophies as well as BACE1 positive dystrophies, the 3D data stacks of fluorescence intensity were analysed using custom-written Matlab software. Initially, local background subtraction was performed to diminish intensity variations among different stacks. Subsequently, a percentile based intensity threshold was applied, and a connected component analysis was used to identify contiguous clusters of voxels. This standard analysis was slightly modified for each of the biological readouts with the detailed analysis described below.

To define **BACE1 positive dystrophies** the 50th percentile of immuno-fluorescence signal was used as threshold for each image stack. Connected component analysis was applied to identify clusters of contiguous voxels and clusters smaller than 1 µm³ were excluded.

4. Materials and Methods

For data stacks of **VGLUT1^{Venus} fluorescence** the 75th percentile was used as threshold. Due to the dense arrangement of VGLUT1-positive structures applying that threshold results in a web-like mask of supra-threshold voxels with nearby structures still merging into one another. Therefore, the data was further segmented morphologically by calculating the distance transformation, followed by watershed segmentation along minimal distance ridges. Subsequently, the minimal diameter as well as the distance to the closest plaque was obtained for each segment. To analyse the distribution of minimal diameter of VGLUT1-positive structures as a function of plaque distance and plaque size, the minimal diameter was binned into 0.2 µm steps. Synapse densities in relation to the distance from plaques were fitted using one-phase association curves.

- $Y(d) = Y_0 + (\text{Plateau} - Y_0) * (1 - e^{-K * d})$, with d = distance to closest plaque and Y = bouton density

The half-distance ($\ln(2) / K$) was obtained as a measure for the sphere of toxic influence of plaques on bouton density.

Amyloid plaques were identified applying the 90th percentile on the Methoxy-X04 fluorescence intensity data. Since amyloid burden typically constitutes 1 to 2 % of brain volume in the imaged region of APPPS1 mice, this threshold is intentionally set to a very low level. It allows to obtain the total size of amyloid plaques as opposed to thresholding operations such as using local contrast or half-width intensity that rather detect the dense plaque core. Subsequently, individual amyloid plaques were tracked over time. For this purpose the image data from consecutive time points was loaded as time series in Imaris (Version 7.7.2, Bitplane). Plaque volumes were extracted by 3D-surface-rendering and were semi-automatically tracked over time using the surface tracking module of Imaris. To identify nucleation events, plaques were tracked back to the first

time point of appearance and were only assessed when present for at least 3 weeks to warrant unambiguous distinction from background signal. Therefore, quantification of plaque density and formation only include values up to 8 weeks post-treatment even though imaging was performed up to 10 weeks. Correct tracking was manually checked for each amyloid plaque. For reliable determination of the actual size of each amyloid plaque the largest extension in XY was determined and the radius was calculated as $radius = \sqrt{area/\pi}$ assuming a spherical shape of plaques (279). The radii of individual plaques were fitted with a monophasic association function, and the radial growth rate at each time point was obtained by calculating the first derivative of the best fit. All plaques contacting the image border were excluded from the analysis. The distribution of presynaptic boutons, presynaptic dystrophies and BACE1 positive dystrophies was analysed with regards to proximity to the closest amyloid plaque. For this purpose, a quasi euclidean 3D distance transformation was performed to identify the distance of every voxel to the closest plaque border. Distance was calculated at 1 μm resolution from the outer border of plaques into surrounding tissue as well as towards the inside of each plaque. Voxels inside plaques were assigned negative distance from plaque border. To quantify the pathological impact of each plaque separately, the 3D volume was divided into sectors with all voxels closest to a particular plaque constituting the sector of that plaque.

For the correlation of plaque formation rate with plaque distance the distance to the closest already existing plaque was determined for each formation event at the respective time point of formation. For the analysis all plaques formed after treatment onset were pooled and closest plaque distance was binned into 20 μm segments. For the frequency distribution of minimal inter-plaque distance,

4. Materials and Methods

the distance to the closest plaque was determined for all plaques at week 10, and inter-plaque distance was binned in 20 µm segments.

9. Curriculum Vitae

| | |
|---------------|---|
| Name | Finn Peters |
| Address | Feodor-Lynen-Str. 17, 81377 Munich, Germany |
| Date of birth | 09.01.1983 |
| E-Mail | finn.peters@med.uni-muenchen.de |

Professional Academic Experience

| | |
|-----------|--|
| 2012-2017 | PhD student at the German Center for Neurodegenerative Diseases (DZNE), Munich, Germany. Doctoral thesis: 'Pharmacological BACE1 inhibitor treatment during early progression of β -amyloid pathology maximizes therapeutic efficacy'; Prof. Jochen Herms, Ludwig-Maximilians University Munich, Germany. |
| 2010-2012 | Research assistant: Prof. Peter Seeburg, MPI for medical research, Department of Neurobiology, Heidelberg, Germany. |

Academic Education

| | |
|-----------|---|
| 2006-2010 | Diploma: 'Biochemistry', Free University of Berlin, Germany. Diploma thesis: 'Analysis of neuronal effector proteins of Drosophila Rab5 and Rab11'; Prof. Claudia Miech and Prof. Volker Haucke, Institute for Chemistry and Biochemistry, Free University of Berlin, Germany. |
|-----------|---|

2005-2006 | **Bachelor of Science:** 'Biochemistry', Université Denis Diderot, Paris, France.

2003-2005 | **Intermediate diploma:** 'Biochemistry', University Hamburg, Germany.

Civile Service

2002-2003 | Young Men's Christian Association (YMCA), Hamburg, Germany.

School Education

2002 | Secondary school leaving examination ('Abitur'), Max Brauer Schule, Hamburg, Germany.

IT Skills

Graphing | GraphPad Prism, Adobe Illustrator

Imaging | ZEN (advanced), Imaris (advanced)

Presentation | MS Office (advanced), Adobe InDesign (advanced)

Coding | Matlab (advanced), Igor Pro, Visual Basic

Languages

German | Native language

English | Fluent

French | Good working knowledge

Professional Training

06.2010 | Course in Basics of Laboratory Animal Science according to FELASA (Category B), University Heidelberg, Deutschland.

Teaching

- | | |
|---------|---|
| 04.2010 | Teaching assistant: ' <i>In vivo</i> two-photon imaging', German Center for Neurodegenerative Diseases (DZNE), Munich, Germany. |
| 2008 | Teaching assistant: ' <i>Introductory course Biochemistry</i> ', Institute for Chemistry and Biochemistry, Free University of Berlin, Germany. |

Congress Participation

- | | |
|------|--|
| 2017 | Oral presentation: 'Pharmacological inhibition of BACE1 reduces amyloid and presynaptic pathology in transgenic Alzheimer mice.' Alzheimer's & Parkinson's Diseases Congress - AD/PDTM, 2017, Vienna, Austria. |
| 2016 | Poster presentation: 'Pharmacological inhibition of BACE1 reduces amyloid and presynaptic pathology in transgenic Alzheimer mice.' Kloster Seeon meeting on BACE proteases in health and disease, near Munich, Germany. |
| 2013 | Oral presentation: 'Long-term <i>in vivo</i> imaging of presynaptic pathology in transgenic Alzheimer mice.' SfN annual meeting, 2013, San Diego, USA. |

Congress Hosting

- | | |
|------|--|
| 2012 | '2nd Heidelberg Forum For Young Life Scientists', Heidelberg, Germany. |
|------|--|

Children

2016 | Jan Lion Asmussen, Munich, Germany.

2013 | Max Anders Asmussen, Munich, Germany.

Salihoglu H, **Peters F**, Rodrigues E, Herzog E, Blume T, Filser S, Dorostkar M, Shimshek D, Brose N, Neumann U, Herms J. "Partial reduction of tau reduces alzheimer plaque in APP transgenic mice."

11. Acknowledgements

I would like to thank Prof. Jochen Herms, for his continuous support of this project, his confidential supervision and many critical discussions. I particularly want to acknowledge the trustful working atmosphere that allowed me to raise two children during the doctoral thesis.

Furthermore, I want to cordially thank Prof. Rainer Uhl who readily agreed to represent this dissertation at the faculty for biology. Special thanks also to Prof. Anja Horn-Bochtler for her interest in this work and the time and effort for preparing the second assessment of this dissertation.

During my doctoral thesis I had the possibility to collaborate with many distinguished scientists. I want to emphasize the collaboration with Novartis and would like to thank Dr. Ulf Neumann for the excellent collaborative work. I want to thank Dr. Severin Filser for his tremendous help on the manuscript, scientific advice and many years of friendship. I am very grateful to Hazal Salihoglu and Tanja Blume who contributed valuable experimental data to finish the project and to Dr. Etienne Herzog and Prof. Nils Brose for allowing me to work with their VGLUT1^{Venus} mouse model.

I also would like to thank Dr. Steffen Burgold and Dr. Carmelo Sgobio for their scientific advice and all people who proof-read this dissertation, in particular my friend Dr. Wilhelm Ching. I furthermore want to acknowledge the excellent technical support provided by Nadine Hoffmann, Eric Grießinger, Sarah Hanselka, Katharina Bayer and Sonja Steinbach, and I thank all colleagues from the animal facility for their commitment and help. For the enjoyable atmosphere

in the lab I want to thank all current and former colleagues from the ZNP and the AG Herms.

I dedicate this work to my wife Marie Asmussen who always encouraged me in my scientific work. Thank you for two wonderful children!
