1. ABSTRACT

Frontotemporal dementia (FTD) is a devastating neurodegenerative disease affecting more than a million people worldwide. Progranulin (PGRN) haploinsufficiency is the primary genetic cause of a subtype of frontotemporal lobar degeneration (FTLD-*GRN*) presenting with behavioral changes and TDP-43 pathology. FTLD-*GRN*, due to its monogenic nature, facilitates studies to better understand the molecular determinants of FTD and to develop novel treatment strategies. Nevertheless, to date, the pathobiology of FTLD-*GRN* is still only partially understood and there is no disease-modifying treatment available.

Several treatment strategies for FTLD-*GRN* are already in clinical development, all aiming to raise PGRN levels in the brain. However, none of them proved efficacy on TDP-43 pathology, behavioral phenotypes, or neurodegeneration. In this study, a novel treatment approach was established by applying a protein replacement approach using recombinant PGRN engineered for transferrin receptor-mediated blood-brain-barrier transcytosis, combined with a liver-targeting adenovirus-associated virus (AAV) gene therapy approach (AAV(L):bPGRN). The AAV(L):bPGRN treatment was tested in two preclinical FTLD-*GRN* models, namely *Grn* knockout (KO), and double KO (DKO) mice, in which both *Grn* and the FTLD-*GRN* risk factor *Tmem106b* are knocked out. The recently described DKO model not only exacerbates the phenotypes of *Grn* KO mice, such as neuroinflammation, lipidome alterations, and autophagic and lysosomal dysfunction. Additionally, DKO mice have a reduced life span, strong neurodegeneration, motor impairment, as well as TDP-43 pathology, a hallmark of FTLD-*GRN*. Using this AAV-based approach, all of the phenotypes in *Grn* KO and DKO mice could be ameliorated or fully reversed. The PGRN replacement strategy was further translated to a human induced pluripotent stem cell (hiPSC)-based model, in which microglia, derived from newly generated DKO hiPSCs, were co-cultured with wildtype neurons. The phenotypes observed in this *in vitro* hiPSC model, such as neuronal degeneration, TDP-43 pathology, and lysosomal dysfunction were all successfully rescued as well. These findings strongly support both PGRN replacement therapy as a promising treatment approach, as well as the DKO mouse model and hiPSC models as useful tools to study FTLD-*GRN*.

The second project addresses a related major open question in the FTD field, which is how loss of PGRN, a lysosomal protein primarily expressed in microglia, eventually leads to TDP-43 pathology in neurons, subsequently resulting in neurodegeneration. The lysosomal protease legumain (LGMN) appears to be a perfect link, as it is critical for the correct maturation of several other lysosomal proteases and was previously shown to be able to process PGRN, as well as TDP-43, into disease-associated fragments. Here, LGMN levels and activity were shown to be increased in both FTLD-*GRN* patient brains and in multiple FTLD-*GRN* models, including hiPSC-derived microglia and, age-independently, in

Abstract

Grn KO mice. *In vitro*, LGMN maturation was slowed down in the presence of full-length PGRN, but matured LGMN rapidly processed PGRN, showing a reciprocal regulation that could be disrupted in FTLD-*GRN*. Given the predominantly microglial expression of LGMN, a pathomechanism was proposed, in which excess LGMN in *GRN* KO microglia could be transferred to neurons resulting in TDP-43 processing and aggregation, as observed in FTLD-*GRN*. To test whether LGMN transfer from microglia to neurons could be possible, neuronal uptake and activation of LGMN from conditioned media by neurons was shown, causing increased TDP-43 processing, which could be ameliorated by LGMN inhibition. AAV-mediated overexpression of LGMN in mouse brain also resulted in increased TDP-43 processing and the accumulation of insoluble phosphorylated TDP-43, as well as motor impairment and neurodegeneration, similarly to the DKO mice. Therefore, LGMN is proved to be an important link between PGRN haploinsufficiency and TDP-43 pathology in FTLD-*GRN*.

In summary, the two studies presented in this thesis address major gaps in the FTD field, establishing LGMN as a link between the loss of PGRN and TDP-43 pathology, and also provide support for PGRN replacement as a disease-modifying therapeutic approach for FTLD-*GRN*.

2. INTRODUCTION

2.1. FRONTOTEMPORAL DEMENTIA – A MULTIFACTORIAL DISEASE

In our ageing society, more and more people are at risk to suffer from neurodegenerative diseases, as age is the main risk factor for developing dementia^{6,7}. After early-onset Alzheimer's disease (AD), frontotemporal dementia (FTD) is the second most prevalent form of presenile dementia, currently affecting around 1.5 million people worldwide (prevalence 15-22 per 100'000 people)^{8,9}. Despite many years of intensive research, there is no disease modifying treatment available due to a lack of understanding of the underlying mechanisms, but also because of the heterogeneity of the disease¹⁰.

Originally, the disease was described by the Czech psychiatrist Arnold Pick as an early-onset form of dementia with atrophy in the frontal and temporal lobes and the presence of so-called Pick bodies¹¹, intracellular neuronal aggregates of the protein tau, characterized by Alois Alzheimer after microscopical examination¹². The next major advances in FTD research did not happen until around 1970, when larger cohorts of non-AD dementia patients were assembled and characterized¹³. Marek-Marcel Mesulam described primary progressive aphasia (PPA), a disease variant that is characterized by gradual language impairment¹⁴. FTD was also further sub-categorized¹⁴ into a spectrum of syndromes, of which the most common is the behavioral variant (bvFTD)^{15,16}, which presents clinically with personality changes, such as apathy, unusual social behavior, language impairment, and overeating¹⁷⁻¹⁹. The pathological spectrum of bvFTD includes neurodegeneration^{11,17}, neuroinflammation^{20,21}, and can present with motor dysfunction^{22,23}. These can partially overlap with other neurodegenerative diseases that belong to the FTD spectrum, such as motor neuron disease (MND)²⁴, corticobasal degeneration (CBD)²⁵, and progressive supranuclear palsy (PSP)²⁵. However, the degeneration of the frontal and temporal cortical lobes (frontotemporal lobar degeneration (FTLD)) is characteristic for FTD^{17,26}. The most common type of MND that also strongly overlaps with FTD symptomatically, pathologically and genetically is amyotrophic lateral sclerosis (ALS)^{27,28}. Because of this overlap, the two diseases are sometimes referred to as the FTD-ALS spectrum^{29,30}. Nevertheless, ALS patients present much more frequently with motor impairments resulting from the loss of upper and lower motor neurons, which is typical for the disease, while FTD patients usually have psychiatric symptoms and dementia^{28,30}. The degree of overlap of symptoms and pathologies across all of these diseases complicates the diagnosis and often the correct identification is only possible after neuropathological assessment^{30,31}.

2.1.1. TDP-43 PATHOLOGY IS A HALLMARK OF MANY FTD, ALS AND AD CASES

Post mortem, extensive research has been performed to dissect disease subgroups based on specific protein aggregation patterns, employing immunohistochemistry, immunoblotting, and electron microscopy techniques. ALS cases predominantly present with intracellular aggregates of transactive response DNA-binding protein of 43 kDa (TDP-43), and much more rarely with fused in sarcoma (FUS) or superoxide dismutase 1 (SOD1) aggregates (Fig. 1A)³². On the other hand, FTD primarily presents with intracellular aggregates of TDP-43 (FTLD-TDP)³³ and of the cytoskeletal protein tau (FTLD-tau)^{34,35}, while fewer FTD cases have aggregated FUS (FTLD-FUS) or aggregates of the ubiquitin-proteasome system (UPS)^{36,37}.

A Pathological inclusions in ALS and FTD

B Genetics of ALS and FTD

FIGURE 1: GENETIC AND NEUROPATHOLOGICAL CONTRIBUTIONS TO THE FTD/ALS SPECTRUM. (A) PERCENTAGE DISTRIBUTION OF THE HISTOPATHOLOGICAL HALLMARKS TDP-43, FUS, SOD1, AND TAU INCLUSIONS, AND AGGREGATES OF THE UBIQUITIN-PROTEASOME SYSTEM (UPS) AGGREGATING IN FTD AND ALS. (B) PERCENTAGE DISTRIBUTION OF DISEASE-CAUSING MUTATIONS ACROSS THE FTD/ALS SPECTRUM. SOD1-MUTATIONS EXCLUSIVELY CAUSE ALS, TDP-43 AND FUS PRIMARILY ALS, WHILE MUTATIONS IN UBQLN2 AND C9ORF72 CAN RESULT IN BOTH FTD AND ALS. TAU AND PGRN ARE EXCLUSIVELY ASSOCIATED WITH FTD. ADAPTED FROM LING ET AL.⁵ (REPRINTED WITH PERMISSION FROM ELSEVIER).

Many disease-causing mutations in the TARDP gene coding for TDP-43 have been identified, especially for ALS but also for FTD³⁸⁻⁴⁰. The protein is ubiquitously expressed and, subcellularly, it mainly localizes to the nucleus, where it is critical for the regulation of transcription, splicing events, and RNA stability⁴¹⁻⁴³. Under stress or disease conditions,

TDP-43 translocates more to the cytosol where several post-translational modifications occur. These include phosphorylation at several sites, C- and N-terminal truncation, as well as ubiquitylation^{33,44-46}. While also playing a role in protein homeostasis, all of these can be identified by immunoblot in the insoluble fraction of brain homogenates of FTD or ALS patients, suggesting a link with the pathology^{47,48}.

With increasing amounts of cytosolic TDP-43, aggregates begin to form that can be visualized by immunohistochemistry³³. The shape and localization of these aggregates and their associated neuronal dystrophy are highly specific and are used in the classification of FTLD-TDP subgroups (FTLD-TDP types A-D)^{31,49}. Type A patients, commonly diagnosed with bvFTD or the non-fluent variant of PPA, have compact cortical and some hippocampal neuronal cytoplasmic inclusions, short dystrophic neurites, as well as sparse nuclear and glial cytoplasmic inclusions. Type B is characterized by smaller neuronal cytoplasmic TDP-43 aggregates and pre-aggregates in deeper cortical layers and also in motor neurons, as well as glial cytoplasmic inclusions. Neuronal inclusions and dystrophic neurites are uncommon for this type, which is associated with patients having both FTD and ALS symptoms. Type C, which is often found in semantic variant PPA patients, shows long dystrophic neurites and compact neuronal cytoplasmic inclusion in the hippocampus, but almost none in the cortex. Glial or nuclear inclusions are also rare. Type D is uniquely found in patients with a mutation in the valosin containing protein gene (*VCP*) and characterized by short dystrophic neurons and neuronal nuclear inclusions^{31,49}.

Through the cryo-electron microscopy of FTLD-TDP and ALS patient brain extracts, the amyloid-like filamentous structure of TDP-43 aggregates was resolved, and it was found to be the same in ALS and FTLD-TDP⁵⁰. A common aggregation mechanism across the disease spectrum is therefore likely. However, further analysis revealed that filaments of type A FTLD-TDP patients are structurally distinct⁵¹, hinting to a potentially different processing and aggregation in this subgroup. Why and how TDP-43 aggregates form still remains an open question. A likely scenario is liquid-liquid phase separation (LLPS), where sequestration of the protein in condensates leads to the formation of aggregation seeds⁵²⁻⁵⁵. This process can be enhanced by post-translational modifications, such as acetylation or phosphorylation, and hindered by RNA binding to the protein^{53,56-58}.

2.1.1.1. PATHOLOGICAL CONSEQUENCES OF TDP-43 AGGREGATION

Whether the aggregation of TDP-43 results in a toxic gain- or loss-of-function is still under debate, however, increasing evidence speaks for a combination of both⁴⁷. Intensive research *in vitro* and *in vivo* has shown that the injection of TDP-43 aggregates in mouse brains, its supplementation in neuronal cultures or its increased expression is neurotoxic^{44,59}. Likewise, the artificial induction of TDP-43 aggregation through the

deletion of its nuclear localization sequence (NLS) or by the introduction of disease-causing mutations was shown to induce cell death in various models^{38,60,61}. Nevertheless, other studies have also shown loss-of-function effects by using models with reduced or depleted TDP-43 levels⁶²⁻⁶⁴. Due to the role of TDP-43 in the nuclear splicing machinery, its knockdown (KD) in neurons impairs the maturation of several of its target gene transcripts, such as *UNC13A* or *STMN2*, and leads to the splicing in of cryptic exons, with either additional or missing RNA stretches⁶⁴. These RNAs can sometimes be translated into cryptic peptides, which can even be detected in the CSF of FTD patients⁶⁵. As an example, TDP-43 loss drastically reduces the levels of stathmin-2 (*STMN2*), a protein involved in axonal maintenance, as its mis-spliced mRNA is degraded, which in turn causes axonal loss⁶⁶. Another example is that of neuronal pentraxin-2 (*NPTX2*), which was shown to be increased – resulting in neurodegeneration – since its expression is regulated by TDP-43 binding to its 3' untranslated region⁶⁷.

Understanding the molecular mechanisms leading to TDP-43 mislocalization and aggregation and their pathological consequences is critical for the development of potential therapeutics. This is not only relevant to ALS and FTD, but also AD, as 30-50% of AD cases present with TDP-43 co-pathology⁶⁸.

2.1.2. FTD IS A DISEASE WITH A STRONG GENETIC COMPONENT

Despite being a highly heterogenous disease, FTD, in a large fraction of all cases, has a strong genetic component. Depending on the study, almost half of all patients have a family history of FTD and 10% of the cases are autosomal dominant⁶⁹. Most genetic cases of FTD/ALS are caused by either hexanucleotide repeats in the chromosome 9 open reading frame 72 (*C9orf72*) or by mutations in the *MAPT* or the granulin (*GRN*) gene (Fig. 1B)⁷⁰⁻⁷⁷. *C9orf72* mutations can lead to either FTD or ALS, always present with dipeptide repeat inclusions and can further present with TDP-43 pathology^{31,72,77}. In contrast, *MAPT* mutations highly selectively cause FTLD-tau with tau inclusions^{73,75,76}. Similarly, *GRN* mutations primarily result in FTLD-TDP type A⁷⁸. Interestingly, *GRN* mutations have also been found as a risk factor for AD and Parkinson's disease (PD), respectively⁷⁹⁻⁸¹.

Much rarer mutations occur in the genes encoding valosin containing protein (*VCP*), charged multivesicular body protein 2B (*CHMP2B*)^{82,83} and TANK-binding kinase 1 (*TBK1*)⁸⁴⁻⁸⁶. Lastly, mutations in the *TARDP* gene, encoding TDP-43, *FUS*, or in the gene encoding ubiquilin 2 (*UBQLN2*) are most commonly causing ALS, but have also been described for FTD or ALS/FTD⁸⁷⁻⁹⁰. All of these proteins are part of the endolysosomal system, suggesting a critical role of the endolysosomal compartment in the pathogenesis of FTD.

2.2. THE ROLE OF PROGRANULIN IN FTLD-TDP

As mentioned before, loss-of-function (LOF) mutations in the *GRN* gene almost always lead to FTLD-TDP⁷⁸. These patients are therefore particularly valuable to investigate potential causes of TDP-43 pathology, the downstream pathomechanisms and the development of treatment strategies. The first mutations were discovered in 2006^{71,74}, and since then numerous additional mutations were identified, mostly leading to a reduction in the protein levels of progranulin (PGRN) by different mechanisms^{71,74,91-93}. These include DNA deletions, missplicing, mutations in the START codon or the introduction of premature STOP codons, leading to nonsense-mediated mRNA decay, all preventing the synthesis of the protein. Additionally, mutations can impair the trafficking of PGRN down the secretory pathway⁹¹⁻⁹³. The reduction caused by LOF mutations can even be detected in patient plasma and is used for diagnosis⁹⁴⁻⁹⁶. Resulting from the heterozygous LOF mutations are haploinsufficiency of the protein and subsequently bvFTD^{71,74}. Homozygous mutations are ultra-rare and cause the lysosomal storage disorder neuronal ceroid lipofuscinosis (NCL), an aggressive form of childhood dementia^{97,98}.

2.2.1. PROGRANULIN – A PROTEIN WITH MANY FUNCTIONS

The *GRN* gene is located on chromosome 17 and encodes for the 593 amino acid-long protein PGRN⁹⁹. It is expressed throughout the whole body, primarily in cells of the hematopoietic lineage¹⁰⁰. In the central nervous system (CNS), it was shown to be primarily expressed in microglia and neurons, with considerably higher levels in microglia^{100,101}. PGRN consists of seven granulin domains and one slightly shorter paraganulin domain⁹⁹. It also comprises a signal sequence for translocation into the secretory pathway where it is matured by heavy glycosylation, resulting in secretion as a 90 kDa protein, instead of the calculated 68.5 kDa (Fig. 2)¹⁰². Originally, PGRN was described as a growth factor in several tissues, and increased levels are associated with wound healing and, in the brain, with neurite outgrowth¹⁰³⁻¹⁰⁵. Additionally, PGRN levels were also found to be increased in several cancers^{105,106}. It was also shown to be anti-inflammatory in a murine model of arthritis¹⁰⁷. In the CNS, PGRN has been described as a neurotrophic factor¹⁰⁸. Once secreted, the protein can further be taken up by cells again and trafficked to the lysosome. Transport into the cell and to the lysosome is mediated either by binding to sortilin or by co-transport with prosaposin *via* the mannose-6-phosphate receptor (Fig. 2)^{109,110}.

FIGURE 2: PGRN SECRETION AND UPTAKE PATHWAYS.

AFTER HAVING UNDERGONE GLYCOSYLATION IN THE ENDOPLASMIC RETICULUM AND GOLGI APPARATUS, PGRN IS DIRECTED TO THE SECRETORY PATHWAY AND RELEASED INTO THE EXTRACELLULAR SPACE. IT CAN THEN BE INTERNALIZED AGAIN AND ENTER THE ENDOLYSOSOMAL COMPARTMENT, EITHER BY BINDING TO SORTILIN OR BY CO-TRANSPORT WITH PROSAPOSIN (PSAP) VIA THE MANNOSE-6-PHOSPHATE RECEPTOR (M6PR). IN THE LYSOSOME, PGRN IS AT LAST PROCESSED INTO SINGLE GRANULINS. ADAPTED FROM TERRYN ET AL.² (REPRINTED UNDER A CC BY LICENCE FROM FRONTIERS).

Within the lysosome, progranulin is rapidly processed into highly stable single and multi-granulins¹¹¹⁻¹¹³. This process can be mediated by cathepsin L (CTSL)^{112,114}. More recently the cathepsins B, K, S, V, E, and G, as well as legumain (LGMN), all present in the endolysosomal compartment, were shown to cleave PGRN *in vitro*¹¹⁵. Outside of the cell, PGRN was also shown to be cleaved by elastase and metalloproteinase-12^{116,117}. However, as partially inhibiting PGRN transport to the lysosome *via* sortilin depletion results in an increase of PGRN levels and reduced levels of granulin peptides, the lysosome seems to be the primary location of intracellular PGRN processing¹¹⁸. The function of the different granulins is not understood yet, however, some evidence hints towards a pro-inflammatory role that might even promote TDP-43 pathology¹¹⁹⁻¹²¹. On the other hand,

a recent preprint claims that overexpression of the granulins A and F in the brains of *Grn* knockout (KO) mice leads to a rescue of the pathological phenotypes¹²².

2.2.2. PROGRANULIN REGULATES LYSOSOMAL FUNCTION

Multiple transport mechanisms of PGRN to the lysosome, its lysosomal processing into granulins, and the lysosomal storage disorder NCL which results from homozygous LOF mutations in the *GRN* gene, all indicate a central role of PGRN in lysosomal biology.

In fact, PGRN is not only processed by different cathepsins, but it has also been shown to act as a chaperone for CTSD during its autocatalytic maturation^{123,124}. *Grn* KO mouse and FTLD-*GRN* patient brains have increased CTSD protein levels and activity, and this has also been observed for CTSB and CTSL¹²⁵⁻¹²⁷. Other studies report decreased CTSD activity in patient-derived fibroblasts and human induced pluripotent stem cell (hiPSC)-derived cortical neurons, implying a potential cell type-specific regulation^{128,129}. Additionally, the levels of the lysosome-associated membrane protein 1 (LAMP1) increase with age in *Grn* KO mice^{126,130}. This might be a compensatory cellular response to maintain lysosomal function, as PGRN was shown to regulate lysosomal acidification which is impaired upon loss of PGRN^{131,132}. In another study, Galectin-3, a protein recruited to damaged membranes, strongly co-localized with lysosomes upon *GRN* KO, a process that could be reversed by addition of PGRN^{133,134}. In hiPSC-derived *GRN* KO neurons and *Grn* KO mouse brains, the lysosomal proteome was drastically altered, including upregulation of cathepsins, proteins involved in autophagy as well as v-ATPases, which mediate lysosomal acidification, and impaired lysosomal protein degradation¹³².

In summary, PGRN is critical for lysosomal homeostasis and its depletion impairs multiple facets of their physiology, which might in turn trigger further downstream pathological changes.

2.2.2.1. REGULATION OF LIPID HOMEOSTASIS BY PROGRANULIN

As the lysosome is a primary location of lipid metabolism, it makes sense to assume a role of PGRN in lysosomal lipid homeostasis¹³⁵. The interaction of PGRN with pro-saposin as part of its lysosomal targeting already suggests an involvement in lipid processing, as the saposins that are derived from prosaposin also mediate glycosphingolipid degradation¹³⁶⁻¹³⁸.

PGRN can also bind to, and thereby stabilize glucocerebrosidase (GCase), the enzyme that primarily metabolizes the glycosphingolipid glucosylceramide^{139,140}. LOF mutations in GCase can cause Gaucher disease, another lysosomal storage disorder, and GCase is further associated with PD^{141,142}. Fittingly, GCase activity is reduced in *Grn* KO mouse and

FTLD-*GRN* patient brains^{133,140,143}. Glucosylsphingosine, another substrate of GCase, was also shown to be strongly elevated in *Grn* KO mice cerebrospinal fluid (CSF) and brains, but only showed a trending increase in FTLD-*GRN* patient CSF¹³³.

The same study reported overall decreased levels of multiple bis(monoacylglycero)phosphate (BMP) species upon PGRN loss, which was also confirmed in patients^{133,144}. This phenotype is described as causative for the reduced GCase activity, as their negatively charged heads could electrostatically sequester the positively charged GCase to membranes within the lysosome and thereby restrict the access to its substrate glucosylsphingosine¹³³. Nevertheless, the reduction in BMP levels is still surprising, as these are usually increased in lysosomal storage disorders¹⁴⁵.

2.2.2.2. THE ENDOLYSOSOMAL PROTEIN TMEM106B IS A RISK FACTOR FOR FTLD-*GRN*

The significance of lysosomal biology in FTLD-*GRN* was further reinforced by the identification of transmembrane protein 106B (*TMEM106B*) as a strong risk gene for FTLD-TDP, and in particular for FTLD-*GRN*, in a genome-wide association study (GWAS), which was confirmed in a case-control study¹⁴⁶⁻¹⁴⁸. The more common allele rs1990622^T increases the risk to develop FTD, while the minor allele rs1990622^C is protective. Interestingly, another coding variant, rs3173615, introduces a T185S replacement, which also decreases disease risk, most likely due to an enhanced degradation of *TMEM106B*^{146,149}. Independently, *TMEM106B* was also identified as a risk factor for multiple other conditions, including neurodegenerative diseases such as AD, PD, ALS and FTLD with C9orf72 repeat expansions¹⁵⁰⁻¹⁵³.

TMEM106B is a type 2 transmembrane protein that is localized in the endolysosomal compartment (Fig. 3)^{154,155}. It is heavily N-glycosylated in its luminal domain and can be regulated through cleavage by lysosomal proteases, forming an N-terminal fragment without the luminal domain, and further cleaved down to an unstable intracellular domain by signal peptide peptidase-like 2a (SPPL2a)^{154,155}.

TMEM106B has several critical roles in endolysosomal organization and trafficking. Upon overexpression of the protein, several studies showed enlarged lysosomes as well as cytotoxicity¹⁵⁴⁻¹⁵⁸. Knockdown of *TMEM106B* in primary neurons caused enhanced retrograde lysosomal transport and dendritic spine degeneration¹⁵⁹. *TMEM106B* is therefore essential for the appropriate dendritic transport of lysosomes, a process mediated by its interaction with microtubule-associated protein 6 (MAP6)¹⁵⁹. Its critical role in lysosomal transport was also shown *in vivo*, as *Tmem106b* KO mice exhibit axonal swellings in Purkinje cells, consisting of heavily enlarged lysosomes, and subsequently Purkinje cell loss^{160,161}. The direct involvement of *TMEM106B* in lysosomal function and protein degradation was shown by one study through increased lysosomal protease

levels, and by another study through raised levels of the autophagy markers p62 and LC3 upon *Tmem106b* KO^{160,162}.

FIGURE 3: SCHEMATIC SHOWING THE STRUCTURE AND PROCESSING OF TMEM106B. TMEM106B IS A LYSOSOMAL TYPE 2 TRANSMEMBRANE PROTEIN WITH SEVERAL N-GLYCOSYLATION SITES IN ITS LUMINAL DOMAIN. IT IS CLEAVED BY LYSOSOMAL PROTEASES INTO AN N-TERMINAL FRAGMENT (NTF) AND A LUMINAL DOMAIN. FURTHER PROCESSING BY SPPL2A RELEASES FROM THE MEMBRANE AN UNSTABLE INTRACELLULAR DOMAIN (ICD) AND A SHORT C-TERMINAL FRAGMENT. ADAPTED FROM FENG ET AL.⁴ (REPRINTED WITH PERMISSION FROM SPRINGER NATURE).

Recently, C-terminal fragments of TMEM106B, cleaved at amino acid 120, were shown to form stable amyloid fibrils in aged individual as well as FTLD-*GRN* patient brains¹⁶³⁻¹⁶⁵. The functional consequences of this fibrillar accumulation remain to be investigated, however, early results indicate that the amount of sarkosyl-insoluble TMEM106B fragments correlates with urea-insoluble phosphorylated TDP-43 (pTDP-43), especially in FTLD type A¹⁶⁶. The same study also confirmed that patients expressing the protective T185S variant had prolonged survival and reduced levels of TMEM106B fragments, providing a potential reason for the protective effect of this variant¹⁶⁶.

2.2.2.3. PGRN AND TMEM106B HAVE AN INTRICATE RELATIONSHIP

As *TMEM106B* is a risk factor for FTLD-*GRN*, the question of how TMEM106B and PGRN interact seems obvious, yet the answer is not as straight forward. When looking at expression levels, FTLD-*GRN* patients have higher *TMEM106B* mRNA and protein levels^{125,146,156}. Likewise, TMEM106B levels are increased in aged *Grn* KO mice, but also in

other conditions of lysosomal dysfunction, as in *Ctsd* KO mice or upon inhibition of lysosomal degradation *via* bafilomycin treatment^{125,154}. On the other hand, overexpression or reduction of TMEM106B levels *in vitro* does not change PGRN levels¹⁵⁴⁻¹⁵⁶. On the contrary, TMEM106B overexpression in another study even reduced processing of PGRN into granulins, most likely due to the induction of lysosomal dysfunction¹¹¹. In *Tmem106b* KO mice, PGRN levels are increased¹⁶⁰. However, in patients carrying the TMEM106B risk allele, plasma PGRN levels were found to be reduced^{94,146,167}.

A study that combined *Grn* KO in mice with the overexpression of neuronal *Tmem106b* showed increased lysosomal dysfunction as well as lipofuscin accumulation, a phenotype that is also present in patients^{128,168}. Combinatorial KO of both *Grn* and *Tmem106b* strongly exacerbated the phenotypes present in *Grn* KO mice in three independent studies^{162,169,170}. These animals present with a drastically reduced life span of four to five months, severe neurodegeneration, neuroinflammation, motor impairments, autophagic defects, as well as myelination deficits^{162,169-171}.

In conclusion, the functions of PGRN and TMEM106B are closely entangled. They can reciprocally influence their protein levels and activity, however, to date they haven't been shown to directly interact with each other. Their co-dependent effect on each other could potentially be explained by their respective strong influence on lysosomal homeostasis.

2.2.2.4. LEGUMAIN – A UNIQUE LYSOSOMAL PROTEASE

As described above, the loss of PGRN has a strong effect on lysosomal homeostasis, especially also through dysregulated cathepsin maturation and activity¹²⁶. Another protein with critical regulatory roles in the lysosome is legumain (LGMN).

The cysteine protease LGMN is also known as asparaginyl endopeptidase (AEP), as it is the only protease in humans that cleaves at the C-terminus of asparagine residues¹⁷². LGMN is expressed as an inactive pro-LGMN that is stable at neutral pH¹⁷². With decreasing pH, LGMN undergoes autocatalytic N- and C-terminal processing to form the mature form of the protein that is most active at pH 4¹⁷²⁻¹⁷⁴. Consequently, pro-LGMN and mature LGMN show distinct localizations in the cell and mature LGMN co-localizes with the lysosomal marker LAMP1¹⁷³. The stability of LGMN is heavily impaired upon increase of pH after its maturation¹⁷².

Within the lysosome, LGMN has been shown to have a central role in the maturation of several lysosomal proteases. In *Lgmn* KO mice, CTSL cannot complete its maturation¹⁷⁵. Another study showed not only the impaired maturation of CTSL, but also that of CTSH and CTSB in the kidney of *Lgmn* KO mice¹⁷⁶. Further observations include weight loss and enlarged lysosomes upon *Lgmn* KO¹⁷⁶.

In neurodegenerative diseases, LGMN was shown to play a role in the processing of the amyloid precursor protein, tau, and alpha-synuclein in *in vitro* cleavage assays¹⁷⁷⁻¹⁷⁹. A more robust link between tau processing by LGMN and tauopathies was established through *in vivo* studies, where the genetic ablation or pharmacological inhibition of LGMN rescued multiple phenotypes in the P301S tau mouse model^{178,180}.

In the context of FTLD-GRN, LGMN was shown to process PGRN *in vitro* amongst other proteases and LGMN activity, while decreased in the inferior occipital cortex (a control region in FTD), was relatively increased within the affected middle frontal gyrus (MFG) in FTLD-GRN patient brains¹¹⁵. Compared to non-demented individuals, however, there was no increase in LGMN activity in the MFG¹¹⁵. Importantly, LGMN is capable of cleaving TDP-43 *in vitro* and liquid chromatography coupled to mass spectrometry (LC/MS) analysis of patient-derived brain material and of various cellular models revealed C-terminal asparagine residues in TDP-43 fragments, strongly supporting the pathological involvement of LGMN in TDP-43 processing¹⁸¹. In addition, almost no fragments of TDP-43 could be detected in *Lgmn* KO mouse brains by immunoblot analysis¹⁸¹.

Taken together, the central role of LGMN in the lysosome together with its capability to process both PGRN, as well as TDP-43 into disease-relevant fragments, presents LGMN as a potential link between PGRN-deficiency and TDP-43 pathology.

2.3. MICROGLIA AND THEIR CRITICAL ROLE IN FTLD-GRN

Microglia were initially described by Pío del Río-Hortega more than a hundred years ago and named based on their small size and supportive function¹⁸². Despite their early discovery, microglia were often neglected in the context of neurodegeneration. However, when large-scale GWAS led to the discovery that immune pathways are centrally involved in neurodegeneration, the field of neuroimmunology, with a special focus on microglia, received increasing attention¹⁸³⁻¹⁸⁶.

Known as the tissue-resident innate immune cells of the brain, microglia constantly surveil their surroundings in the adult brain for potential infiltrates or injuries by sensing changes in the extracellular composition, but also *via* direct cell contact (Fig. 4)¹⁸⁷⁻¹⁹⁰. However, they already have critical functions during development. After migration to the brain from the yolk sac, microglia support the appropriate development of neuronal circuits^{191,192}. Developing neurons express complement (C)1q and C3 at synapses in an activity-dependent manner, and microglia prune inactive synapses *via* phagocytosis^{192,193}. This process has been shown to be essential to refine brain circuitry during development, but it also continues to be active throughout the lifespan^{194,195}. Similarly, microglia recognize dying neurons through neuronal ATP release and a lack of fractalkine (CX3CL1) expression. These environmental changes can be sensed *via* the microglial fractalkine

receptor, P2Y purinergic receptors for ATP, or also Tyro3, Axl and Mer (TAM) receptor signaling^{194,196,197}. Among their other roles, microglia also release brain-derived neurotrophic factor (BDNF) to support neurogenesis and neuronal survival in development and adulthood^{198,199}.

FIGURE 4: OVERVIEW OF MICROGLIAL FUNCTIONS.

BY EXECUTING THEIR FUNDAMENTAL FUNCTIONS OF SURVEILLANCE, PHAGOCYTOSIS AND THE RELEASE OF SOLUBLE FACTORS, MICROGLIA ARE INVOLVED IN MANY PROCESSES IN THE BRAIN. THESE INCLUDE MYELINATION, NEUROGENESIS, SYNAPSE REMODELING, MODULATION OF NEURONAL ACTIVITY, TISSUE REPAIR, BBB MAINTENANCE AND REPAIR, VASCULOGENESIS, AND INFLAMMATION. (REPRINTED FROM PAOLICELLI ET AL.³ WITH PERMISSION FROM ELSEVIER).

In addition to their roles in the regulation of neural plasticity, neuronal homeostasis, and tissue surveillance, microglia further support correct myelination through the removal of aberrant myelination, as well as regulating the general pool of oligodendrocyte precursor cells^{200,201}. Moreover, vascularization in both the brain and the eye are also regulated by microglia²⁰²⁻²⁰⁴. In the adult brain microglia ensure blood-brain barrier (BBB) integrity by creating an anti-inflammatory milieu through cytokine release in homeostasis, but also by the physical closure of lesions that are sensed *via* their purinergic receptors^{205,206}.

2.3.1. MICROGLIA AT THE CENTER OF NEURODEGENERATION

As microglia constantly surveil their environment looking for potential changes, they are also rapidly responding to any abnormality. This reactivity was originally described as a morphological transition from highly ramified homeostatic cells, to 'activated', more ameboid cells in disease conditions¹². Nowadays, microglia are seen as highly dynamic

cells that respond uniquely to different challenges by adopting different transcriptomic, proteomic and metabolomic signatures¹. A microglia state shared by many neurodegenerative diseases, is that of disease- or damage-associated microglia (DAM), originally described by Keren-Shaul *et al.* in an amyloid pathology model using single-cell RNA sequencing²⁰⁷. This microglial population emerges from the homeostatic microglia, induced by upregulation of triggering receptor expressed on myeloid cells 2 (TREM2)²⁰⁷. Since then, similar signatures have been identified in different disease models, as well as in patients, and during normal ageing²⁰⁸⁻²¹¹. Reactive microglia can have beneficial functions, like neurotrophic support, phagocytosis of pathological aggregates and of apoptotic or degenerating cells^{212,213}. However, they can also create a pro-inflammatory neurotoxic milieu through the release of cytokines and complement components^{212,214,215}. This pro-inflammatory environment can further stimulate other cells, such as astrocytes, to adopt a neurotoxic phenotype²¹⁶. The beneficial and detrimental roles of microglia in the context of neurodegenerative diseases have been extensively discussed by the community and are still under debate²¹⁷⁻²²². The consensus is, however, that microglia play a central role in the dynamics of neurodegeneration¹. This is further supported by genetics, since multiple GWAS studies have identified mutations in microglial genes as factors in a variety of neurological diseases¹⁸³⁻¹⁸⁶.

2.3.2. THE ROLE OF MICROGLIA IN FTLD-GRN

Besides the fact, that PGRN is primarily expressed by microglia in the CNS and shows only low expression levels in astrocytes and neurons, there are multiple other reasons why microglia play a critical role in FTLD-GRN^{126,223}. To start, different studies have shown increased numbers of ionized calcium-binding adapter molecule 1 (IBA1)-positive microglia, as well as increased expression of the microglial phagocytic activation marker CD68 in FTLD-GRN patient brains compared to C9orf72 mutation carriers and healthy controls^{224,225}. FTLD-GRN patients also show an increased intensity of the neuroinflammation and microglial activation marker translocator protein (TSPO) in positron-emission-tomography (PET), compared to sporadic FTLD^{226,227}. By applying a combination of single-nucleus RNA sequencing and Nanostring transcriptomics of thalamus and frontal cortex of FTLD-GRN patients and controls, Marsan *et al.* could show dramatic changes in microglial gene expression, especially in the thalamus²²³. Differentially expressed genes (DEGs) include the general microglial markers *TMEM119* and *CXCR1*, as well as the activation markers *CD68*, *C1QA/B/C* and *C3*²²³.

Additionally, by using *Grn* KO mice, several other publications also showed microglial activation in disease. Transcriptional analysis revealed a characteristic gene signature, similar to the DAM state, but also comprising a number of differentially expressed lysosomal genes^{169,223,226,228,229}. Many of these markers could be confirmed by

immunofluorescence staining²²⁸. Single-cell RNA sequencing further indicates an age-dependent increase in microglia numbers²²⁸. This increase, as well as the phagocytic activity marker Cd68 and several other microglial activation markers, such as ApoE, Clec7a, and Trem2 were also reported in other studies^{133,226}. Götzl *et al.* further confirmed the increase in TSPO PET intensity, as observed in FTLD-GRN patients, in *Grn* KO mice²²⁶.

Functionally, loss of PGRN in mice was shown to increase the pro-inflammatory cytokines tumor necrosis factor (TNF) and IL-6 in microglia²³⁰. Microglia *in vivo* as well as primary *Grn* KO microglia were shown to have increased levels of the complement proteins C1q, C3, and C3b²²⁹. Consequently, primary *Grn* KO microglia excessively prune synapses of co-cultured primary neurons and synaptosomes from aged *Grn* KO mice, contain high levels of C1q and C3²²⁹. In another study, media transfer from *Grn* KO primary microglia to primary neurons resulted in TDP-43 mislocalization to the cytosol and cytotoxicity²²⁸. Interestingly, all of these phenotypes could be rescued by genetic ablation of C1q, C3, or both, arguing in support of a central role of complement-mediated neuron-microglia crosstalk in the pathogenesis of FTLD-GRN^{228,229}.

On a side note, microglial activation in FTLD-GRN is not necessarily entirely pathogenic, as genetic ablation of Trem2, the protein necessary for the DAM state transition, on top of a *Grn* KO mouse background, resulted in drastically worsened neurodegeneration, as quantified *via* neurofilament light-chain (NfL) measurements in the CSF²³¹.

2.4. THERAPEUTIC APPROACHES FOR FTLD-GRN

To date, there is no disease-modifying treatment available in the clinic for either FTD or FTLD-GRN patients. However, research efforts are under way both to deepen the molecular understanding of the disease, as well as to translate these findings into potential drug candidates. There are several promising approaches in preclinical and clinical development for FTLD-GRN, all attempting to raise PGRN levels in order to rescue the disease-causing haploinsufficiency of the protein (Fig. 5).

Clinically, the most advanced along the trial pipeline is an anti-sortilin antibody in phase III^{232,233}. This molecule aims at preventing the sortilin-mediated uptake of extracellular PGRN and its subsequent trafficking to the lysosome, thereby increasing extracellular levels. This approach was able to normalize plasma and CSF PGRN levels in FTLD-GRN patients to the levels of non-mutation-carriers^{232,233}. However, as discussed, PGRN executes many functions within the lysosome and prevention of lysosomal transport might have an overall negative effect on disease outcome.

FIGURE 5: OVERVIEW OF THE THERAPEUTIC APPROACHES FOR FTLD-GRN CURRENTLY IN CLINICAL DEVELOPMENT.

OVERVIEW OF THE THREE THERAPEUTIC APPROACHES FOR FTLD-GRN THAT ARE CURRENTLY IN CLINICAL DEVELOPMENT. PTV:PGRN (IN ORANGE) IS A PROTEIN REPLACEMENT THERAPY USING PGRN ENGINEERED TO BIND THE TRANSFERRIN RECEPTOR (TFR) FOR RECEPTOR-MEDIATED TRANSCYTOSIS THROUGH THE BBB AND ENHANCED DELIVERY TO THE BRAIN. AN ANTI-SORTILIN ANTIBODY (IN GREEN) PREVENTS SORTILIN-MEDIATED TRANSPORT OF PGRN INTO THE CELL AND TO THE LYSSOSOME, THUS INCREASING EXTRACELLULAR PGRN LEVELS. AAV-BASED GENE THERAPY APPROACHES (IN BLUE) ENABLE LOCAL EXPRESSION AND SECRETION OF PGRN IN THE BRAIN. ADAPTED FROM SIMON ET AL.³ (REPRINTED UNDER A CC BY NC ND LICENCE FROM ELSEVIER).

Another promising approach is adenovirus-associated virus (AAV)-mediated gene therapy. Two approaches are currently in clinical development and both aim for *cisterna magna* injection of an AAV expressing PGRN^{234,235}. In *Grn* KO mice, both approaches strongly increased CSF PGRN levels and ameliorated pathological phenotypes^{234,235}. AAV-mediated delivery was also recently shown to work when expressing single granulins¹²². In non-human primates, only expression by ependymal cells was shown as well as increased CSF and plasma PGRN levels²³⁵. A possible concern with this approach is the limited brain biodistribution of both the virus and the expressed PGRN, which was reported to be problematic in larger animals²³⁶⁻²³⁸. The virus only transduces the outer cortical layers, and thus PGRN can only be secreted and taken up locally in these brain regions. In fact, a recent mouse study employing an AAV-based approach to increase PGRN levels *via* direct CNS delivery could rescue the pathology in the spinal cord, but did not show an effect on brain pathology in an FTLD-GRN mouse model²³⁹. A *cisterna magna* injection also risks injuring the brain or the viral capsid itself could raise immune reactions^{236,240}.

Lastly, a recombinant brain-penetrant PGRN replacement therapy is also in clinical development¹³³. The molecule PTV:PGRN consists of recombinant PGRN fused to a protein transport vehicle (PTV), a modified Fc fragment that can bind to the transferrin receptor (TfR), thus enabling receptor-mediated transcytosis through the BBB. Under physiological conditions, the BBB is only weakly permeable to large molecules, but PTV:PGRN was shown to have a roughly five-fold-increased brain penetrance compared to a non-TfR-binding PGRN control^{133,241}. Using primary bone marrow-derived macrophages (BMDMs), hiPSC-derived microglia, as well as *Grn* KO mice, a study showed, after PTV:PGRN administration, rescue of lysosomal defects, lipid aberrations, and gliosis¹³³. A potential concern is the prevention of endogenous transferrin binding to its receptors, which was, however, not observed in a previous study applying the transport vehicle technology²⁴².

In conclusion, the molecules in development for the treatment of FTLD-*GRN* have great potential. However, none of the studies has conclusively addressed the effect of treatment on FTLD-*GRN* hallmarks such as TDP-43 pathology, defects in protein degradation, behavioral changes, and neurodegeneration.

2.5. AIMS OF THE STUDY

Despite many years of research, there is no disease-modifying treatment available for FTD. The first project presented in this thesis addresses gaps in the field through the following questions:

Is PGRN replacement therapy a feasible approach to treat FTLD-*GRN*?

- Is it possible to apply a gene therapy approach for peripheral expression of brain-penetrant PGRN to raise PGRN levels in the brain?
- Does this approach rescue disease-relevant phenotypes, such as TDP-43 pathology, neurodegeneration and behavior phenotypes, in the *Grn x Tmem106b* double knockout mouse model?
- Can FTLD-*GRN* pathology be modeled *in vitro* using hiPSC-derived *GRN x TMEM106B* double knockout neuron-microglia co-cultures and can these phenotypes be rescued with PGRN replacement?

LOF mutations in *GRN*, a gene primarily expressed by microglia, eventually lead to TDP-43 pathology primarily in neurons. This spatial paradox is addressed in the second project in this thesis:

How does the loss of PGRN cause TDP-43 pathology in FTLD-*GRN*?

- Does the loss of PGRN result in the increase of a specific lysosomal protease, which can also cleave TDP-43 and whose activity can be regulated by PGRN itself?
- Can this lysosomal protease be transferred from microglia to neurons?
- Does this transfer subsequently cause TDP-43 pathology in neurons?

3. RESEARCH ARTICLES

3.1. RESCUE OF FTLD-ASSOCIATED TDP-43 PATHOLOGY AND NEURODEGENERATION BY PERIPHERAL AAV-MEDIATED EXPRESSION OF BRAIN-PENETRANT PROGRANULIN

Research article 1:

Author contributions:

Conceptualization: MR, MJS, MSK, SLD, JWJ, AC, GDP, CH

Methodology: MR, MJS, IP, GW, SR, SSD, GL, LSc, LSp, SB, TL, MS, MSK, JHS, TS, SLD, JWJ, DP, AC, GDP, CH

Investigation: MR, MJS, BP, CS, IP, GW, SR, SSD, GL, LSc, LSp, SB, BN, KB, JHS, TS

Visualization: MR, MJS, IP, JHS, TS

Funding acquisition: DP, CH

Project administration: DE, MS, JWJ, DP, AC, GDP, CH

Supervision: MR, MJS, GW, SR, JHS, TS, LSc, LSp, SB, DP, AC

Writing – original draft: MR, MJS, GDP, CH

My author contributions in detail:

I planned and executed the DKO mouse treatment study – this included coordination of the mouse cohort, performing *i.v.* tail vein injections for AAV-delivery, blood collections from the facial vein and longitudinal rotarod measurements. I executed the flipping test, hindlimb clasping test and organ collection with the help of GW. For all *post mortem* analyses, I planned the experiments. I further post-processed the brains for cryosectioning

which I performed with the help of LSc and subsequently established and performed immunofluorescence stainings. I imaged the sections partially with the help of IP. For biochemical analyses, I pulverized the tissues and subsequently performed western blot analysis with the help of CS, a student under my supervision. I also planned and coordinated the ELISA and SIMOA experiments that were performed by KB and BN. I performed the preliminary Nanostring that made us decide to perform bulk RNA sequencing. In general, I led the communication with our collaborator Denali Therapeutics regarding this study including study design, material exchange, and experimental coordination. For the RNA sequencing and lipidomics analysis specifically, I worked closely with TS and JHS on data interpretation and presentation.

For the hiPSC experiments, I cloned the required constructs and performed genome editing of the *TMEM106B KO* and DKO cell lines, including genotyping and quality controls. I performed the initial characterization of microglia, neurons, and co-cultures derived from these cells and established a series of pathological readouts. Under my supervision, BP, a master's student, performed the treatment of these cultures with PTV:PGRN followed by biochemical analysis. I performed the immunofluorescence stainings and imaging for this study.

For all experiments performed with DKO cells or animals, I interpreted and quantified the results (besides the imaging) and prepared the figures for this manuscript. For the other figures, I received help from MJS. I wrote the first draft of this manuscript with the help of CH, MJS and GDP and incorporated the comments from all authors for the final version.

Rescue of FTLN-associated TDP-43 pathology and neurodegeneration by peripheral AAV-mediated expression of brain-penetrant progranulin

One sentence summary:

Peripheral AAV-mediated delivery of brain-penetrant PGRN rescues TDP-43 pathology, neurodegeneration and motor phenotypes in FTLN-GRN models.

40

Abstract:

Progranulin (PGRN) haploinsufficiency is a major risk factor for frontotemporal lobar degeneration with TDP-43 pathology (FTLD-*GRN*). Multiple therapeutic strategies are in clinical development to restore PGRN levels in the CNS, including gene therapy. However, a limitation of current gene therapy approaches aimed to alleviate FTLD-associated pathologies may be their inefficient brain exposure and biodistribution. We therefore developed an adeno-associated virus (AAV) targeting the liver (L) to achieve sustained peripheral expression of a transferrin receptor (TfR) binding, brain-penetrant (b) PGRN variant (AAV(L):bPGRN) in two mouse models of FTLD-*GRN*, namely *Grn* knockout and *GrnxTmem106b* double knockout mice. This therapeutic strategy avoids potential safety and biodistribution issues of CNS-administered AAVs while maintaining sustained levels of PGRN in the brain following a single dose. AAV(L):bPGRN treatment reduced several FTLD-*GRN* associated disease pathologies including severe motor function deficits, aberrant TDP-43 solubility and phosphorylation, dysfunctional protein degradation, lipid metabolism, gliosis and neurodegeneration in the brain. Translatability of our findings was confirmed in a novel human *in vitro* model using co-cultured human induced pluripotent stem cell (hiPSC)-derived microglia lacking PGRN and TMEM106B and wild-type hiPSC-derived neurons. As in mice, aberrant TDP-43, lysosomal dysfunction and neuronal loss were ameliorated after treatment with exogenous TfR-binding protein transport vehicle fused to PGRN (PTV:PGRN). Together, our studies suggest that peripherally administered brain-penetrant PGRN replacement strategies can ameliorate FTLD-*GRN* relevant phenotypes including TDP-43 pathology, neurodegeneration and behavioral deficits. Our data provide preclinical proof of concept for the use of this AAV platform for treatment of FTLD-*GRN* and potentially other CNS disorders.

Main text:

65 INTRODUCTION

Haploinsufficiency of progranulin (PGRN) caused by heterozygous loss-of-function (LoF) mutations in the *GRN* gene dramatically enhances the risk for FTLD-TDP (*1-3*). As in all TDP-43 proteinopathies, FTLD with PGRN deficiency (FTLD-*GRN*) displays aggregation, pathological processing and abnormal phosphorylation of TDP-43 (*4, 5*). FTLD-*GRN* patients present with
70 severe clinical symptoms associated with underlying neurodegeneration primarily in the cortex (*5, 6*), resulting in enhanced neurofilament light chain (NfL) levels in blood and cerebrospinal fluid (CSF) (*7-9*), as well as pronounced neuroinflammation and dysfunction of the endo-lysosomal system (*5, 10, 11*). PGRN deficiency is hypothesized to contribute to these pathologies through its established role in lysosomal function (*11-14*), microglia homeostasis (*15-17*) and inflammatory
75 signaling (*11, 18, 19*) (reviewed in (*4, 5, 20, 21*)). PGRN or its proteolytic derivatives, the granulin peptides, are localized within the endo-lysosomal system (*22, 23*) and are implicated in the regulation of lysosomal proteases (*11, 12, 24-27*), lysosomal pH (*14, 28, 29*) as well as lipid hydrolases, such as glucocerebrosidase (GCase) (*29-34*). Loss of PGRN in mice causes an age-dependent increase in lysosomal enzymes, lysosomal membrane proteins, hyperactivated microglia
80 and saposin D, indicating deficits in endolysosomal and autophagic protein degradation (*11-19, 25, 29-33, 35, 36*). Lysosomal phenotypes further include deficiency of endolysosomal anionic phospholipid bis(monoacylglycero)phosphate (BMP) and secondary storage of sphingolipids, such as GCase substrates and gangliosides (*29, 33, 37*). Consistent with its critical role in the lysosome, homozygous LoF mutations in *GRN* cause the fatal lysosomal storage disease (LSD) termed
85 neuronal ceroid lipofuscinosis (NCL) in humans (*38, 39*).

Grn^{+/-} (*Grn* HET) mice present with no robust disease-relevant phenotypes (*12, 40*). In contrast, *Grn*^{-/-} (*Grn* KO) mice recapitulate lysosomal and inflammatory FTLD-*GRN* pathologies but exhibit only minor TDP-43 pathology even at advanced ages (*12, 16, 19*). Furthermore, behavioral phenotypes in *Grn* HET and *Grn* KO mice are subtle and have limited relevance to
90 FTLD-*GRN* clinical phenotypes (*40, 41*). We and others recently developed a mouse model that addressed some of the limitations of the *Grn* KO model by introducing an additional KO of *Tmem106b* (*42-44*), a genetic risk factor for FTLD-*GRN* (*45*). TMEM106B is involved in endo-lysosomal degradation and trafficking (*46-50*) and has been shown to undergo processing and give rise to a C-terminal fragment prone to forming fibrils which are observed in the brain of FTLD-

95 *Grn* patients and aged individuals (51-53). The *Tmem106b* and *Grn* double KO (DKO) generally exacerbates phenotypes observed in the single KOs, including lysosomal and autophagic dysfunction, neuroinflammation, and myelin loss (42-44, 54). Importantly, unlike the *Grn* KO, it exhibits much more robust accumulation of insoluble and hyperphosphorylated TDP-43, and motor impairment at an age of 4 months (42-44). Thus, this model reproduces key biochemical, cell
100 biological as well as disease-relevant motor and neurodegeneration phenotypes of FTLD-*Grn*.

To date, there is no disease-modifying treatment for FTLD-*Grn*, although several therapeutic approaches are currently being tested in the clinic (reviewed in (20, 55)). Given that it is a monogenic disease, correcting the PGRN deficiency with a protein replacement therapy may offer an effective therapeutic approach to slow or halt disease progression and reduce pathology.
105 While adeno-associated virus (AAV)-based therapies are under clinical investigation (56-58), they typically rely on direct CNS administration, which may introduce safety concerns as well as result in limited or uneven biodistribution of the AAV (56-58) (reviewed in (59)). Thus, the number of cells expressing PGRN and PGRN exposure in cells far from the injection site might be insufficient. Consistent with this, a recent study suggests that AAV1 and 9 administered to the CSF can reduce
110 disease phenotypes in the spinal cord, but not in the brain of an FTLD-*Grn* mouse model, limiting their use for neurodegenerative diseases with widespread brain pathologies, such as FTLD-*Grn* (60). As an alternative, we recently fused human recombinant PGRN to a transport vehicle (PTV:PGRN), enabling transferrin receptor (TfR)-mediated transcytosis across the blood-brain barrier (BBB) and delivery throughout the whole CNS (29). Using PTV:PGRN, multiple FTLD-
115 related pathologies in *Grn* KO mice and human microglia – lipid/lysosomal abnormalities, microglial/astrocytic hyperactivation – were rescued (29). However, due to the limited pathology of the *Grn* KO mouse model, TDP-43 pathology, motor deficits and neurodegeneration could not be investigated.

Here, we developed an advanced gene therapy approach by using a liver-targeting (L)
120 adeno-associated virus expressing brain-penetrant (b) PGRN (AAV(L):bPGRN). This strategy combines a TfR-mediated, brain-penetrant PGRN biologic with AAV-targeted delivery to the liver, enabling brain-wide PGRN delivery with a single peripheral administration treatment paradigm without requiring direct CNS injection. We tested the AAV(L):bPGRN approach in *Grn* KO mice as well as in our recently described DKO mouse model lacking both *Grn* and *Tmem106b* to study
125 whether PGRN replacement could rescue TDP-43 pathology, motor impairment, exacerbated

neuroinflammation, neuronal loss, impaired protein degradation, and lipidomic and transcriptomic changes in the brain. To complement our *in vivo* efforts, we generated a hiPSC-derived FTL model by co-culturing *GRN* and *TMEM106B* DKO human iPSC-derived microglia (iMG) with WT human iPSC-derived neurons (iN). This model recapitulates multiple *in vivo* phenotypes, including
130 microglial hyperactivation, lysosomal abnormalities, aberrant TDP-43 processing and phosphorylation, as well as neurodegeneration. Strikingly, our replacement strategy significantly reduced all phenotypes observed in the DKO mice and human iPSC model, despite the phenotypic severity and constitutive loss of *TMEM106B*.

Our study provides compelling evidence that brain-penetrant PGRN replacement therapies
135 such as AAV(L):bPGRN or PTV:PGRN can have an impact on the central pathologies of FTL-*GRN* in the brain, namely TDP-43 pathology and neurodegeneration, in both mouse and human FTL models.

RESULTS

140 AAV(L):bPGRN allows safe and robust expression and brain delivery

We generated AAV(L):bPGRN, a liver-targeting AAV8 encoding a fusion protein (8D3:PGRN) consisting of a single chain fragment variable (scFv) antibody recognizing mouse transferrin receptor (TfR; 8D3) fused to human PGRN (hPGRN). AAV(L):bPGRN infects hepatocytes in the liver where it stably expresses 8D3:PGRN after a single peripheral administration to provide
145 sustained expression and secretion of the fusion protein into systemic circulation (Fig. 1A). As a proof-of-principle, we first confirmed AAV(L):bPGRN treatment drives stable expression of 8D3:PGRN in *Grn* KO mice. We infected 4-5-month-old WT and *Grn* KO mice with AAV(L):bPGRN and monitored hPGRN levels in liver, brain and plasma for 31 weeks (Fig. 1B). In the liver of AAV(L):bPGRN treated mice, hPGRN levels of 5 $\mu\text{g}/\text{mg}$ above background were
150 observed 9 weeks after dosing, suggesting robust liver targeting of AAV(L):bPGRN (Fig. 1C). Furthermore, one week after injection, hPGRN was detectable in plasma and after 4 weeks, expression stabilized at an average of 3 $\mu\text{g}/\text{ml}$ (Fig. 1D), demonstrating that the liver expressed AAV(L):bPGRN is secreted into circulation. Finally, robust levels of hPGRN were detected in the brain of mice at both 9 and 31 weeks after injection, supporting efficient blood-brain-barrier
155 transecytosis of the fusion protein (Fig. 1E).

As high levels of AAV infection have been linked to adverse effects, including hepatotoxicity (61), and TfR is highly expressed on immature red blood cells (RBCs) we evaluated serum chemistry (including alanine transaminase (ALT) and aspartate aminotransferase (AST)) and hematology (including circulating reticulocytes), and performed histopathologic analysis of key organs from *Grn* KO mice treated with AAV(L):bPGRN after 31 weeks (Fig. S1, Table S1). No significant microscopic findings were noted in the assessed tissues, including brain, liver, heart, and sciatic nerve (Table S1). No treatment-related findings were identified in serum. Minimal and non-adverse changes were observed in hematology, including slight decrease in red blood cell size (mean corpuscular volume (MCV)) and hemoglobin (mean corpuscular hemoglobin (MCH)) levels, accompanied by a slight increase in RBC and reticulocyte counts (Fig. S1A-D). Thus, a single injection of AAV(L):bPGRN in mice allows for sustained brain delivery of hPGRN without any significant deleterious side-effects.

Fig. 1: AAV-expressed PGRN is delivered to the brain and shows no side effects in *Grn* KO mice. (A) Graphical summary of treatment paradigm. Intravenously administered AAV expresses brain-penetrant (b) human progranulin (PGRN) in the liver (L) (AAV(L):bPGRN). PGRN is fused to a single chain fragment variable (scFv) antibody recognizing mouse transferrin receptor (TfR; 8D3). 8D3:PGRN is expressed by liver hepatocytes, released into the vasculature and can cross the blood-brain-barrier *via* transferrin receptor-binding. (B) Schematic of AAV treatment and sample collection in the *Grn* KO AAV treatment study. Directly after treatment, blood was sampled weekly (x4 = 4 times in 4 weeks (wks)), from 16 weeks after treatment on every 4 weeks. (C-E) hPGRN levels in liver (C), plasma (D) and brain (E) following AAV(L):bPGRN treatment in mice. For tissues, 9-week samples are depicted on the left and 31-week on the right. For all figures, error bars represent standard error of the mean (SEM). n=5-6/group.

180 **AAV(L):bPGRN is stably expressed in DKO mice and ameliorates motor defects**

We next examined the effects of AAV(L):bPGRN mediated PGRN replacement in DKO mice. Previously, we demonstrated that DKO mice not only exacerbate the FTLN-related pathologies observed in *Grn* KO mice, but additionally exhibit motor impairment, and pronounced abnormal phosphorylation and deposition of insoluble TDP-43 (42-44). To determine whether restoring
185 PGRN is sufficient to prevent these phenotypes, DKO mice were injected at 6 weeks of age, prior to development of robust pathologies. A predetermined treatment duration until an age of 15 weeks was established due to the severity of the DKO phenotypes (Fig. 2A) (42). As early as 4 weeks after AAV delivery, stable levels of hPGRN of around 4 $\mu\text{g/ml}$ were observed in plasma of treated WT and DKO mice (Fig. 2B). Robust hPGRN protein levels were also detected in liver and brain
190 of treated mice (Fig. 2C,D), without affecting endogenous expression of mPGRN (Fig. S2A-C).

Given that motor impairment is a common symptom observed in FTLN-*Grn* patients and in DKO mice (62-64), our initial objective was to evaluate whether the administration of AAV expressing 8D3:PGRN could alleviate these phenotypes. Therefore, we conducted a longitudinal assessment of rotarod performance, commencing three days after AAV injection. While initially,
195 all mice performed at a comparable level, WT animals increased time on the rotarod over 15 weeks regardless of treatment. In contrast, performance of both DKO and AAV-treated DKO mice decreased over time (Fig. 2E). However, AAV treatment significantly slowed the rate of decline in DKO mice, and in contrast to untreated DKO mice, AAV treated DKO mice never failed the test (rotarod time <3 s). To further assess motor function, we performed a flipping test at 15 weeks,
200 evaluating righting ability. In this paradigm, saline-treated DKO mice could be flipped over, while most AAV-treated DKO mice could not be flipped or raised themselves immediately (Fig. 2F, Fig. S3A, Movie S1-4). We further conducted the hind limb clasping test (42, 65) and found that treated DKO mice showed significantly reduced hind limb clasping compared to untreated DKO mice, with some mice not exhibiting any clasping phenotype (score = 0) (Fig. 2G, Fig. S3B). In
205 conclusion, AAV driven expression of 8D3:PGRN substantially lowered severe motor neuron deficits in the DKO mice.

Fig. 2: AAV-expressed PGRN is delivered to the brain and ameliorates behavioral abnormalities in DKO mice. (A) Schematics of AAV treatment and sample collection in the *Grn* x *Tmem106b* double knockout (DKO) AAV(L):bPGRN treatment study. (B-D) hPGRN levels in plasma (left, n=7/group; 6, 10 and 15-week-old), liver (middle, n=4-6/group; 15-week-old) and brain (right, n=7/group; 15-week-old) following AAV(L):bPGRN treatment in mice as assessed by ELISA. (E) Longitudinal assessment of rotarod performance following treatment. (F) Quantification of the flipping test based on a scoring system (n=7/group). (G) Quantification of the hind limb clasping test based on a scoring system (n=7/group).

Data is depicted as mean \pm standard deviation (SD), data points represent individual animals. For E, overall comparison was performed by two-way ANOVA with Tukey's multiple comparison. Individual groups in E were compared using two-tailed student's t-test. For F and G, one-way ANOVA with Tukey's multiple comparison was performed. ns p > 0.05, **p < 0.01, ****p < 0.0001.

AAV(L):bPGRN reduces proteolysis defects, TDP-43 pathology and neurodegeneration

Based on the correction of functional motor deficits, we hypothesized AAV(L):bPGRN treatment may also correct the endolysosomal and autophagic protein degradation defects observed in the DKO mice (42-44). These mice present with an increase in ubiquitinated proteins in the brain (Fig. 3A,B), indicating defects in proteolysis by the ubiquitin/proteasome pathway. Moreover, the lysosomal sphingolipid-activator protein prosaposin, its functionally active cleavage product saposin D, and the autophagosome cargo protein p62 are all upregulated, suggesting endolysosomal and autophagy dysregulation (Fig. 3A,B) (66, 67). The accumulation of insoluble p62 and both LC3 I and its lipid modified form LC3 II, key players in the autophagy pathway (67), indicates the formation of pathological autophagic aggregates (Fig. 3A,B) (68). Immunofluorescence detection of p62 confirmed the presence of these aggregates (Fig. 3C,D). Strikingly, all these protein degradation-related phenotypes were significantly reduced in treated DKO mice compared to untreated animals (Fig. 3A-D).

DKO mice also exhibit TDP-43 pathology (42-44), a hallmark of FTLN-GRN that is observed in patients' brains (69, 70), but is not robustly replicated in *Grn* KO mice (11, 19). This includes insoluble TDP-43 deposits, abnormal processing and phosphorylation of the protein (42-44, 71). Upon analyzing solubility, processing and phosphorylation of TDP-43 by sequential extraction and subsequent biochemical analysis, we only observed mild changes in protein levels and processing of TDP-43 in the high salt- and RIPA-soluble fraction (Fig. S4A-D). However, protein levels of insoluble TDP-43 (urea fraction) were consistently increased in DKO mice compared to WT mice, and this phenotype was completely reversed following AAV treatment (Fig. 3E,F). Additionally, we found a drastic increase of the pathological insoluble and phosphorylated TDP-43 (pSer409/410) in DKO mice compared to WT which was reduced by 70% in AAV(L):bPGRN-treated DKO mice (Fig. 3E,F). Because TDP-43 pathology is generally associated with neurodegeneration, we measured plasma neurofilament light chain (NfL) levels, a clinical marker for neurodegeneration (7, 8), before and during treatment. Initially, plasma NfL levels were comparable between WT and DKO mice. However, while NfL levels rose over time in DKO mice, they were significantly lower in treated DKO animals as early as 4 weeks after treatment and even decreased after 9 weeks (Fig. 3G). At 12 months of age, *Grn* KO mice only showed a mild increase in plasma NfL, but substantial increase of NfL in the CSF which was also rescued upon treatment with AAV(L):bPGRN (Fig. S4E).

Together, these findings demonstrate a robust reduction of TDP-43 pathology, associated with a rescue of the impaired protein degradation machinery, motor phenotypes, and reduced neurodegeneration following treatment with AAV(L):bPGRN.

AAV(L):bPGRN reduces gliosis *in vivo*

275 Previous studies demonstrated that gliosis and neuroinflammation are hallmark pathologies not only in *Grn* KO (12, 16, 19) and the DKO mouse models (42-44), but also in FTLD-*GRN* patients (5, 72). To investigate if these pathological phenotypes could also be rescued by AAV(L):bPGRN treatment, we examined the transcriptional profile of *Grn* KO and DKO mice following AAV(L):bPGRN treatment. In 12-month-old *Grn* KO mice, bulk brain RNA sequencing analysis
280 demonstrated mild transcriptional changes consistent with previous reports (12, 15, 16, 19, 29), which in turn were partially corrected with AAV(L):bPGRN (Fig. S5A). In 4-month-old DKO animals however, these changes were drastically exacerbated, consistent with previous reports (42-44). Projected into two dimensions via multi-dimensional scaling, samples from WT animals (with or without AAV treatment) clustered together, indicating globally similar gene expression profiles,
285 but DKO samples segregated according to genotype and treatment (Fig 4A). AAV treatment of DKO animals shifted the corresponding samples toward those of WT animals, indicating partial correction of the transcriptional differences. We next completed gene-level differential expression analysis. We found that in DKO mice, 481 genes were up- and 304 genes downregulated compared to WT animals (Fig. S6A). Following AAV(L):bPGRN treatment, 51 genes were down- and 171
290 genes upregulated again in DKO mice (Fig. 4B). Pathway analysis revealed that the most impacted genes include established markers for disease-associated microglia (DAM) and lysosomal dysfunction (Fig. 4C) (12, 73). Interestingly, while the expression of many of these markers was fully corrected with AAV(L):bPGRN, some genes only showed partial response to treatment (ex:*Serpina3n*), suggesting *Tmem106b*-specific effects that are not responsive to PGRN
295 replacement. Others, like *Ccl2*, showed an AAV response, regardless of genotype. As both DKO and treatment strongly modulated the abundance of known cell type markers such as *Gfap* (astrocytes) and *Itgax* (microglia) (Fig. 4B), we next determined changes in cell type composition (74) (Fig. S6B,C). Both, microglia and astrocyte markers were greatly increased in the DKO mice and showed a marked reduction with AAV treatment. In contrast, DKO brains had a reduction in
300 neuronal cell type markers that are elevated with AAV treatment. Interestingly, different established oligodendrocyte markers displayed different gene expression changes across genotypes and treatments, perhaps reflecting differential responses in cellular subtypes. To confirm the significant reduction in gene expression associated with microglia and astrocyte activation following PGRN replacement, we further assessed the expression of *Gfap*, *Iba1* and *Cd68* by

305 immunohistochemistry (Fig. 4D,E). In DKO mice, both the total number of microglia and Cd68⁺
reactive microglia, as well as astrocytes, were significantly elevated. Consistent with the RNA
sequencing data, PGRN replacement resulted in a significant reduction of astrocytes. While the
number of microglia was only slightly reduced, the proportion of Cd68⁺ microglia was substantially
decreased (Fig. 4D,E). We further assessed the levels of Trem2, a microglial surface receptor that
310 is critical for the transition to reactive microglia (73, 75, 76). The markedly elevated levels of
Trem2 in plasma, liver and brain of DKO mice were all effectively decreased after PGRN
replacement (Fig. 4F), consistent with a reduced microglial response to the pathological challenges
after treatment-related amelioration. In *Grn* KO mice, comparable elevations of Cd68, Iba1 and
Trem2 were also responsive to AAV(L):PGRN treatment, supporting the link between PGRN and
315 glial function (Fig. S5B-D).

AAV(L):bPGRN rescues lipid biomarkers of FTLD-GRN

Previously, *Grn* KO mice were found to exhibit robust alterations of lipid metabolism and lysosomal function (29). Here, we sought to determine if AAV(L):bPGRN can restore lipid changes. We first confirmed that 12-month-old *Grn* KO mice exhibit dysregulation of the phospholipid BMP and the glycosphingolipid glucosylsphingosine. Similar to recombinant PGRN replacement (29), AAV(L):bPGRN treatment restored these lipids back to baseline levels (Fig. S7A,B). Next, due to the established role of *Tmem106b* in the endolysosomal pathway (46-50), we hypothesized that the lipid profile of DKO mouse brain may be similarly or even more dysregulated. To assess this, we performed targeted lipidomic assessment of DKO and WT mouse brain with or without AAV(L):bPGRN treatment (Fig. 5). Unsupervised principal component analysis (PCA) of 203 lipids detected showed clear separation between WT and DKO mice along the principal component (PC) 1 axis. Lipid profiles of AAV(L):bPGRN-treated DKO mice shifted closer to WT conditions indicating a partial correction (Fig. 5A). Univariate analysis of lipid alterations in DKO mice brain relative to WT identified 27 significantly dysregulated lipids including several lipid classes such as gangliosides (GM1, GM2, GM3, GD3), glycerophospholipids (BMP, lysophosphatidylglycerol (LPG), phosphatidylinositol (PI)), sterols (cholesteryl ester, CE) and sphingolipids (S1P, Cer) (Fig. 5B,C). Of these, 19 lipids were responsive to AAV(L):bPGRN treatment with varying sensitivity (Fig. 5B-E). AAV(L):bPGRN treatment broadly increased BMP species of varying acyl-chain compositions back to WT levels (Fig. 5F). AAV(L):bPGRN treatment significantly lowered levels of galactosylsphingosine, which accumulates when galactosyl ceramidase (*Galc*) is impaired. The broad upregulation of gangliosides in *Grn* KO mice such as GM3, was also observed in DKO mice and further exacerbated by additional increase of GM2 and GM1 species and partially rescued upon treatment (Fig. 5G). The more robust ganglioside accumulating phenotype of DKO mice relative to *Grn* KO alone (Fig. S7) and only partial rescue upon AAV(L):bPGRN treatment suggests that *TMEM106B* may have a more dominant influence over lysosomal ganglioside catabolism. Also unique to DKO, there was an increase in myelin-associated lipids, CE and galactosylceramide (GalCer). Accumulation of these lipids potentially reflects the significantly altered myelin homeostasis in the DKO brain (Fig. 5H) (42, 77, 78). Taken together, these data highlight that DKO mice have severe lipid dysregulation that is largely corrected with PGRN replacement using AAV(L):bPGRN.

PTV:PGRN rescues FTLN-like pathology in human neurons and microglia

375 To test whether our findings can be translated to human cells and to enable investigation of cell-
autonomous versus non-autonomous effects, we extended our experiments to human induced
pluripotent stem cells (hiPSC). First, we generated a DKO hiPSC line by knocking out *TMEM106B*
in our recently described *GRN* KO cell line using an established CRISPR/Cas9 editing workflow
(Fig. S8) (79, 80). To establish a hiPSC-based FTLN model, we co-cultured DKO hiPSC-derived
380 microglia (iMG) with WT hiPSC-derived neurons (iN) (Fig. 6A). Crosstalk between these two cell
types is expected as microglia express the highest PGRN levels of all brain cell types, whereas
TDP-43 pathology is mostly observed in neurons (71). Upon co-culture of DKO iMG together with
WT iN we observed a significant increase in TDP-43 processing and phosphorylation (Fig. 6B,C),
resulting in pronounced disruption of the neuronal network as shown by a reduction in MAP2⁺ area
385 (Fig. 6D,E). Lastly, we replicated our recently reported finding in *GRN* KO monocultured iMG
showing dysfunctional lysosomes (29, 32). We found a strong elevation of the protein expression
levels and catalytic activities of the lysosomal proteases cathepsin B, D and L (CTSB, CTSD,
CTSL) in the co-cultures (Fig. 6F-H). As the *in vivo* mechanism of action of AAV(L):bPGRN
cannot be replicated in a cell culture system, we applied PTV:PGRN (29) to the co-culture model
390 to confirm therapeutic effects of PGRN replacement on TDP-43 pathology and neurodegeneration
in a human system. Following a 5-day co-culture, we treated the cells with either PTV:PGRN, an
inactive human IgG control (IgG) or PBS as control every second day until collection after 2 weeks
(Fig. 6A). The cultures treated with PTV:PGRN showed partially normalized levels of PGRN, with
fully reversed aberrant TDP-43 processing and disruption of the neuritic network (Fig. 6B-E).
395 Moreover, the increased levels of pTDP-43 and lysosomal proteases as well as their increased
activity were also reduced (Fig. 6B,C,F-H).

Taken together, PGRN replacement in a human model successfully alleviates disease
associated phenotypes and supports the applicability of our newly developed hiPSC-derived FTLN
model for developing therapeutic approaches.

DISCUSSION

Currently, there are several candidate therapeutic approaches for FTLD-*GRN* in clinical trials or
420 preclinical development, all aiming to raise PGRN protein levels (reviewed in (20, 55)). These
include an anti-sortilin antibody to increase circulating PGRN levels *via* inhibition of cellular
uptake (81-83), AAV-based gene therapy approaches (84-86), a recombinant brain-penetrant
PGRN biologic (29), as well as small molecules and transcriptional regulators (87). Here, we tested
425 an innovative approach for a PGRN replacement therapy using a second-generation gene therapy
approach in two different mouse models for FTLD-*GRN*, namely *Grn* KO and *GrnxTmem106b*
DKO mice, that combines the dosing advantages of AAV approaches with the biodistribution
improvements allowed by TfR-mediated transcytosis at the BBB and brain delivery of recombinant
fusion proteins.

Despite several decades of research, mouse models reproducing TDP-43 pathology
430 associated with FTLD-*GRN* without overexpression have been a major limitation in the field. Since
Grn HET mice do not show any robust biochemical, pathological or behavioral phenotypes (11,
40), we took advantage of our recently developed model, which employs KO of *Grn* in combination
with a KO of *Tmem106b* (42). This model was previously shown to reproduce abnormal
phosphorylation and deposition of insoluble TDP-43, which are a central pathological hallmark of
435 FTLD-*GRN*. This mouse model also exhibits profound motor phenotypes, in addition to
exacerbating the phenotypes seen in *Grn* KO mice including deficits in protein degradation, lipid
and transcriptome alterations, gliosis, and neurodegeneration (42-44).

In our study, a single injection paradigm resulted in successful AAV-mediated expression
of a TfR-binding PGRN biologic (8D3:PGRN) in the periphery (*i.e.*, liver), which was robustly and
440 sustainably delivered to the brain. This resulted in amelioration of the TDP-43 phenotypes within
the brain. Furthermore, levels of endolysosomal lipid BMP, which was recently described as a
pathway biomarker downregulated in *Grn* KO mice (29, 33), were fully restored. Levels of GM3
and GM2, which were upregulated in DKO mice were ameliorated as well, suggesting that the
secondary storage of gangliosides observed in *Grn* KO mice is also responsive to PGRN
445 replacement, despite the loss of *Tmem106b* (29, 33). Autophagic and lysosomal protein
dysregulation was ameliorated as well. Transcriptomic and immunohistochemical analyses further
indicated that microglia and astrocyte reactive states were significantly dampened. Altogether,
these beneficial treatment effects were associated with a longitudinal decrease of plasma NfL, a

biomarker for neurodegeneration which is commonly used in clinical practice (8). Lastly, the severe
450 motor phenotypes in DKO mice, which started shortly after treatment, were substantially reduced.
In contrast to other therapeutic strategies, which enhance circulating levels of PGRN by inhibiting
cellular uptake (*e.g.*, the anti-sortilin antibody Latozinemab) (83), our approach increases both
extracellular and intracellular PGRN. The latter is believed to be critical, as PGRN or its
455 proteolytically generated granulins exert crucial functions within the endolysosomal pathway,
which may be compromised by inhibition of cellular uptake of PGRN (22, 88).

We also verified the PGRN replacement strategy in a novel human iPSC-derived cellular
model consisting of WT neurons co-cultured with *GRN/TMEM106B* DKO microglia. This model
is based on the observation that *GRN* is predominantly expressed in microglia, whereas TDP-43
pathology primarily occurs in neurons (71, 89, 90). Microglial/neuronal crosstalk is in line with
460 recent findings showing that complement factors secreted by *Grn* KO mouse microglia increase
cell death and aberrant TDP-43 in mouse cortical neurons (19). Thus, we expected non-cell
autonomous effects on neurons caused by loss of PGRN in microglia, which we indeed observed
in our human co-culture system. Upon treatment with PTV:PGRN, disease-relevant abnormal
posttranslational modification of TDP-43 and lysosomal dysfunction as well as neuronal loss were
465 strongly ameliorated in the co-cultures, demonstrating applicability of this human model system to
test efficacy of PGRN replacement.

Our toxicological evaluation of serum chemistry and hematology, as well as
histopathological analysis did not show any significant adverse events and demonstrated that
application of the brain-penetrant biologic AAV(L):bPGRN appears safe in mice at least for 31
470 weeks of treatment. This is of foremost importance, since mice intraventricularly injected with
AAVs expressing PGRN showed neuroinflammation (56). Another caveat with protein
replacement therapy is the impermeability of the BBB for AAVs or larger proteins, such as PGRN.
Therefore, current therapeutic approaches investigated in the clinic rely on lumbar or cisterna
magna CSF injection (86), which can cause injury to the medulla (57), and, despite direct delivery
475 into the CNS, exhibit biodistribution limited to regions adjacent to CSF (58). This was also shown
recently where direct CNS delivery of AAV1 and 9 expressing PGRN in a mouse model of FTL-
GRN resulted in amelioration of phenotypes in the spinal cord, but not in the brain (60).

Due to the severity of the DKO phenotypes, we employed a preventive subchronic treatment
paradigm shortly before pathologies occur, while treating *Grn* KO animals in a chronic treatment

480 paradigm. As genetic testing combined with measurements of plasma PGRN and NfL levels may allow for diagnosis of asymptomatic *GRN* mutation carriers before they convert to the clinical stage of the disease, prevention trials with PGRN replacement therapies may potentially be applied before clinical symptoms arise. Taken together, our findings strongly support the application of brain-penetrant PGRN as replacement therapy in FTLD-*GRN* patients. Furthermore, since our
485 approach ameliorates lysosome-related deficits within the brain, similar brain penetrant therapeutics approaches may be developed for other lysosomal disorders with a neuronopathic component.

A limitation of our study is that by definition, the effect of PGRN replacement on TMEM106B fibrils (51-53) or of molecules aiming to increase PGRN levels, could not be
490 addressed using this model due to the full loss of PGRN and TMEM106B. Another limitation of our and other models for TDP-43 pathology is the sparse TDP-43 mis-localization and nuclear clearance (19, 42). However, the biochemical TDP-43 phenotypes closely resemble those observed in patients (71).

495 MATERIALS AND METHODS

Animal experiments and mouse brain tissue

All animal experiments were performed either according to German animal welfare law and approved by the government of upper Bavaria (Vet_02-17-106) or by the Denali Therapeutics Institutional Animal Care and Use Committee. Mice were kept under standard housing conditions;
500 standard pellet food and water was provided *ad libitum*. AAV was applied intravenously *via* tail vein injection (max. 200 μ l). For tissue collection, mice were anesthetized with either Ketamine/Xylazine or tribromoethanol. Whole blood was either terminally collected via cardiac puncture or during the study via facial vein puncture and transferred into EDTA-coated tubes before centrifugation at 12,700 rpm for 7 min at 4°C. The plasma fraction was used for analysis. In cases
505 where CSF was drawn, it was obtained by cisterna magna puncture and spun down at 12,700 rpm for 7 min at 4°C to minimize blood contamination. Mice were transcardiacally perfused with chilled PBS before organ collection. Tissues and fluids were stored at -80°C until further use.

510 **Generation and maintenance of WT and *GRNxTMEM106B* DKO iPSC lines**

Experiments using hiPSC were performed following all relevant local guidelines and regulations. The iPSC line A18944 was purchased from Thermo Fisher (A18945). For the generation of *GRNxTMEM106B* DKO iPSC lines, our previously described *GRN* KO iPSC line was used (32). Cells were kept in Essential 8 Flex media (Thermo Fisher, A2858501) on vitronectin-coated
515 (Thermo Fisher, A3349401) cell culture dishes at 37°C, 95% humidity and 5% CO₂. Cells were detached as colonies at 70% confluency using PBS with 0.5 mM EDTA and passaged subsequently.

CRISPR/Cas9 genome editing

Human iPSC were edited as previously described (80, 91) with modifications. In brief, CRISPOR (<http://crispor.tefor.net>) (92) was used to design gRNAs and for the determination of putative off-
520 target loci. To cover most of the coding region of the *TMEM106B* gene locus, exon 2 was targeted close to *de novo* STOP codons in alternate reading frames.

Cells were cultured as single cells on Geltrex (Thermo Fisher Scientific, A1110501) in StemFlex™ media (Thermo Fisher Scientific, A3349401) supplemented with ROCK inhibitor (Selleck-chem, S1049) for two days prior to electroporation. They were harvested using Accutase (Thermo Fisher
525 Scientific, A1110501) and resuspended in 20 µl P3 nucleofector solution (Lonza) before addition to a pre-incubated ribonucleoprotein complex of gRNA (60 pmol) and Cas9 (30 pmol, Integrated DNA Technologies) protein. Using a Nucleofector (Lonza) with program CA-137, cells were electroporated and grown on Geltrex in StemFlex™ media with ROCK inhibitor until colonies appeared. Single colonies were picked and expanded upon Sanger sequencing verification of
530 successful KO. Successful editing was further confirmed by Western blot. Quality controls were performed to confirm the absence of off-target effects (by PCR for the 10 most likely hits based on MIT and CFD scores on CRISPOR), the absence of loss of heterozygosity (nearby SNP sequencing), pluripotency of the novel cell line (immunofluorescence staining for OCT4, NANOG, SSEA4 and TRA160) and chromosomal integrity by molecular karyotyping (LIFE & BRAIN
535 GmbH).

Differentiation of human iPSC-derived Microglia (iMG)

Cells were differentiated into iMG following the protocol initially presented by Abud et al. (93), with the modifications we recently published (32). On day 24 of differentiation, cells were used for co-cultures with iN.

540 ***Differentiation of human iPSC-derived Neurons (iN)***

Cells were differentiated into cortical neurons (iN) according to our recently published protocol, following a dual-SMAD inhibition approach (94). On day 60 of differentiation, iN were used for co-cultures with iMG.

Co-culture of iMG and iN and PTV:PGRN treatment

545 For co-cultures, iMG and iN were cultured together at a 1:8 ratio. The required amount of iMG were collected and spun down as for passaging before resuspending in 50% of the required iN media, supplemented with double the concentration of the cytokines needed for iMG identity, namely hIL34 (Peprotech, 200-34), hM-CSF (Peprotech, 300-25) and hTGF- β (Peprotech, 100-21). 50% of the media was removed from the iN and the fresh media containing the iMG added.
550 From then on, 50% media without doubling the cytokine concentration was replaced every other day before cell processing for experiments on day 14 of co-culture.

To test the efficacy of PTV:PGRN in our model, cells were treated with either PBS or 100 nM inactive human IgG as a control, or 100 nM PTV:PGRN (29) starting on day 5 of co-culture every other day until collection.

555

Design and generation of AAV(L):bPGRN

The mature protein expressed by AAV(L):bPGRN was designed by genetically fusing a mouse TfR binding scFv (8D3) to the N-terminus of full-length human PGRN. A human influenza hemagglutinin (HA) tag and 2x Gly4Ser linker were included between the scFv and PGRN to
560 provide an additional handle for detection (HA tag) and to impart flexibility between the two proteins. Mature PGRN was used for the fusion protein, with N- and C-terminal breakpoints of T18 and L593, respectively; numbering as outlined in UniProt P28799. The fusion protein was cloned into a plasmid under an ApoE/AAT1 promoter, with a terminal WPRE to enhance expression, and flanking AAV2 ITRs. After generating the viral cis plasmid, recombinant AAV8 was generated
565 and characterized by Signagen. The virus was titered by rtPCR quantification of genome copies. Endotoxin quantification was also performed and measured at less than 0.05 u/ml. Virus was delivered to animals as described above at a dose of 1.3×10^{13} vg/kg,

Motor function assessment of DKO mice

570 All motor tests were performed blinded.

Rotarod test

Motor function was assessed using a rotarod (TSE Systems, 3376O4R), accelerating from 4-40 rpm within 300 s as previously described (42). Mice were trained twice within one week before longitudinal assessment twice per week. The average of three consecutive tests was calculated for
575 each recording day.

Flipping test

Mice were recorded while being slightly poked to assess balance. Mice were scored based on showing no change in balance (0), trembling (1), flipping over and standing up within 3 seconds (2), or flipping over and not standing up within 3 seconds (3).

580 ***Hind limb clasp test***

Mice were recorded while being lifted by their tail as previously described (65). They were scored based on no cramping of the hind limbs (0), cramping for less than 25% (1), more than 25% (2) or more than 50% of the recording time.

585 **Toxicity assessment**

Assessment of toxicity was based on body weight, serum chemistry, hematology, necropsy and microscopic evaluation of select organs. Whole blood and serum were collected for complete blood count (CBC) and serum chemistry, respectively. Samples were evaluated at Quality Veterinary Laboratories (QVL). A complete necropsy was performed by qualified staff, and brain, heart, lung,
590 liver, kidney, spleen, small and large intestine, prostate, testes, femur/tibia (including bone marrow) and sciatic nerve were collected into 10% buffered formalin. For tissue histopathology, tissues were processed to H&E-stained slides at Cureline Biopathology. Histology slides were reviewed by a board-certified veterinary pathologist, and instances of abnormal tissue observations were recorded.

595

Gene profiling of total brain

Total RNA was extracted from frozen brain powder using the Qiagen RNeasy plus kit (Qiagen, 74034). Quality and quantity were assessed with a 4200 TapeStation System (Agilent). Next generation sequencing libraries were generated using the QuantSeq 3' mRNA-seq Library Prep Kit FWD for Illumina sequencing with the UMI second strand synthesis module (Lexogen). Library concentration and quality were assessed with the 4200 TapeStation system (Agilent). The libraries were pooled in equimolar ratios for sequencing on an Illumina NovaSeq 6000 instrument. Raw sequencing data (FASTQ files) were processed with skewer (version 0.2.2) (95) to trim sequencing adapters. Unique molecular identifiers (UMIs) were extracted from each read with the umi2index tool (Lexogen). Quality control of the trimmed reads was performed using FastQC (version 0.11.5) (96). Reads were aligned to the mouse reference genome (version GRCm38_p6) with STAR (version 2.7.1a) (97), using an index created with the `-sjdbOverhang=50` argument. Splice junctions from Gencode gene models (release M17) were provided via the `-sjdbGTFfile` argument. Alignments were obtained with the following parameters: `-readFilesCommand zcat -outFilterType BySJout -outFilterMultimapNmax 20 -alignSJoverhangMin 8 -alignSJDBoverhangMin 1 -outFilterMismatchNmax 999 -outFilterMismatchNoverLmax 0.6 -alignIntronMin 20 -alignIntronMax 1000000 -alignMatesGapMax 1000000 -quantMode GeneCounts -outSAMunmapped Within -outSAMattributes NH HI AS nM MD XS -outSAMstrandField intronMotif -outSAMtype BAM SortedByCoordinate -outBAMcompression 6`. Reads sharing the same UMI and genomic coordinate were deduplicated using the `collapse_UMI_bam` tool (Lexogen). Post-alignment quality control reports were generated using MultiQC (version 1.0) (98). The raw gene expression matrix was constructed from the 'forward' column of STAR's `ReadsPerGene.out.tab` output files using R (version 4.3). Gene symbols and biotype information were extracted from the Gencode GTF file. For downstream analysis, library size factors were determined using TMM normalization (99) across all genes annotated as `protein_coding` with the edgeR R package (version 3.42.4) (100). Exploratory and differential expression analysis was performed with the edgeR and limma (version 3.56.2) (101) R packages. Multidimensional scaling was performed based on the top 500 most variable genes with the `plotMDS` function, after removing batch effects with `removeBatchEffect` function. For differential expression analysis, a linear model with fixed effects for experimental group, sex and batch covariates was fit to all protein-coding genes with the `voomLmFit` function, including sample weights. Contrasts of interest were extracted

with the eBayes function with robust priors (e.g., by setting robust=TRUE). Genes with a false discovery rate (fdr) of less than 5% and a fold change of at least 20% were considered to display a significant genotype or treatment effect. Significant genotype x treatment interactions were called by applying a 15% fdr threshold. To visualize genes whose expression was perturbed in the double-knock out samples and also showed correction after AAV treatment, their normalized, batch-corrected expression was plotted with the ComplexHeatmap R package (version 2.16.0) (102). We found that in the DKO mice, *Grn* expression was still detected by our 3' mRNA sequencing approach, but protein PGRN was absent confirming successful knockout as previously described (11, 15, 42).

Lipid analysis by liquid chromatography-mass spectrometry (LCMS)

Lipidomic analyses were largely performed as previously described (29). Approximately 20 mg tissue were homogenized for 30 sec at 25 Hz at 4°C in 400 µl of LC-MS grade methanol containing 2 µl internal standard mix solution. Homogenized samples were centrifuged at 21,000 g for 20 min at 4°C. Cleared methanolic supernatants were kept at -20°C for 1 h. Samples were centrifuged at 21,000 g for 10 min at 4°C and supernatants dried under a constant stream of N₂. Dried samples were stored at -80°C until analysis. For analysis and separation of glucosylceramides and galactosylceramides, 50 µl of above extracts were dried under constant stream of N₂ for 4 h and resuspended in 200 µl of 92.5/5/2.5 LCMS grade acetonitrile/isopropanol/water fortified with 5 mM ammonium formate and 0.5% formic acid.

Samples extracted above were analyzed using three different lipidomics assays, namely 1) lipidomics positive, 2) lipidomics negative and 3) glycosphingolipid positive panels. All of these assays were performed using the Agilent 1290 Infinity UPLC system coupled to Sciex 6500+ QTRAP mass spectrometer. All data acquisition was performed in multiple reaction monitoring mode (MRM) with the collision energy (CE) values reported in Table S2 and S3. Lipids were quantified using a mixture of non-endogenous internal standards as reported in Table S2 and S3. All quantification was performed using MultiQuant 3.02 software (Sciex). Chromatography and mass spectrometer settings used are described below:

Lipidomics positive: Mobile phase A consisted of 60:40 acetonitrile/water (v/v) with 10 mM ammonium formate + 0.1% formic acid; mobile phase B consisted of 90:10 isopropyl alcohol/acetonitrile (v/v) with 10 mM ammonium formate + 0.1% formic acid. Source settings for

positive mode were as follows: curtain gas at 40 psi; collision gas was set at medium; ion spray
660 voltage at 5500 V; temperature at 250°C; ion source Gas 1 at 55 psi; ion source Gas 2 at 60 psi;
entrance potential at 10 V; and collision cell exit potential at 12.5 V.

Lipidomics negative: Mobile phase composition was same as in positive mode with the exception
that 10 mM ammonium acetate and 0.1% acetic acid were used as fortificants. Source settings were
as follows: curtain gas at 30 psi; collision gas was set at medium; ion spray voltage at -4500 V;
665 temperature at 600°C; ion source Gas 1 at 55 psi; ion source Gas 2 at 60 psi; entrance potential at
-10 V and collision cell exit potential at -15.0 V.

Lipidomics analysis in positive and negative ionization modes were initiated with 5 µl of sample
injection using a BEH C18 1.7 µm, 2.1×100 mm column (Waters) as stationary phase with 0.25
mL/min flowrate and column temperature set at 55°C. The gradient was programmed as follows:
670 0.0-8.0 min from 45% B to 99% B, 8.0-9.0 min at 99% B, 9.0-9.1 min to 45% B, and 9.1-10.0 min
at 45% B.

Glucosylsphingolipid panel in positive mode: Mobile phase A consisted of 92.5/5/2.5
ACN/IPA/H₂O with 5 mM ammonium formate and 0.5% formic acid. Mobile phase B consisted
of 92.5/5/2.5 H₂O/IPA/ACN with 5 mM ammonium formate and 0.5% formic acid. For each
675 analysis, 5 µL of sample was injected on a HALO HILIC 2.0 µm, 3.0 × 150 mm column (Advanced
Materials Technology, PN 91813-701) using a flow rate of 0.48 mL/min at 45°C. Mobile phase A
consisted of 92.5/5/2.5 ACN/IPA/H₂O with 5 mM ammonium formate and 0.5% formic acid.
Mobile phase B consisted of 92.5/5/2.5 H₂O/IPA/ACN with 5 mM ammonium formate and 0.5%
formic acid. The gradient was programmed as follows: 0.0–2 min at 100% B, 2.1 min at 95% B,
680 4.5 min at 85% B, hold to 6.0 min at 85% B, drop to 0% B at 6.1 min and hold to 7.0 min, ramp
back to 100% at 7.1 min and hold to 8.5 min. Glucosylceramide and galactosylceramide were
identified based on their retention times and MRM properties of commercially available reference
standards (Avanti Polar Lipids, Birmingham, AL, USA). Table S4 shows specific analytes and
internal standards used in this assay.

685 Integrated areas of endogenous lipids were divided by areas of spiked in stable isotope internal
standards. Specific pairings of endogenous lipid to class level internal standards are described in
Table S2-4. For all analysis, raw area ratio data was log₂ transformed and filtered to retain variables
that are present in at least 70% of samples. Missing values were imputed using the kNN method
using the 5 nearest donor variables. Unwanted variations in the dataset were adjusted for using the
690 RUV4 method. Genotype, treatment and genotype-treatment interaction effects on lipids were

assessed using a robust linear model with sex, batch, and RUV4 regression factors as covariates in the model. Top contrast results were visualized using heatmaps, boxplots or volcano plots. Bar plots of mean differences of selected analytes were created using GraphPad Prism. All analyses were performed using R statistical software (version 4.0.2; R Core Team 2020).

695

Protein analysis and Western blotting

Mouse hemispheres were mechanically pulverized before sequential protein extraction as previously described (11).

Initially, brain samples were lysed in high salt lysis buffer (0.5 M NaCl, 10 mM Tris pH 7.7, 5 mM EDTA, 1mM DTT, 10% sucrose) and incubated on ice for 15 min followed by centrifugation. The supernatant was used as high salt fraction, the pellet was resuspended in RIPA lysis buffer (150 mM NaCl, 20 mM Tris pH 7.4, 2.5 mM EDTA, 0.1% (w/v) SDS, 1% (v/v) NP-40, 0.25% Na-deoxycholate) and incubated on ice for 15 min followed by centrifugation. The supernatant was used as RIPA fraction, the pellet was resuspended in urea lysis buffer (30 mM Tris pH 8.5, 7 M urea, 2 M thiourea, 4% CHAPS) and processed as before generating the urea fraction as supernatant after centrifugation. All lysis buffers were supplemented with PhosStop™ phosphatase inhibitor cocktail (Roche, 04906837001), protease inhibitor cocktail (Merck, P8340) and Benzonase® (EMD Millipore, 70746-4).

Material from hiPSC was lysed in RIPA lysis buffer for 20 min on ice before centrifugation. Protein concentration was determined using BCA protein assay (Thermo Fisher Scientific, 23225). Equal amounts of protein were diluted in Laemmli buffer and separated by SDS-PAGE before transfer onto polyvinylidene difluoride or nitrocellulose membranes (both GE Healthcare Science). After primary antibody incubation (Progranulin (clone 8H10, (11)), Calnexin (Stressgen, SPA-860), Ubiquitin (Cellsignaling, 3936), p62 (MBL, PM045), LC3 (Novusbio, NB100-2220), Saposin D ((103)), TDP-43 NT (Proteintech, 10782-2-AP), TDP-43 CT (Proteintech, 12892-1-AP), pTDP-43 (Proteintech, 80007-1-RR), b-Actin (Sigma-Aldrich, A5316), Progranulin (Thermo Fisher Scientific, 40-3400), TUJ1 (Biolegend, 801201), IBA1 (Gentex, GTX100042), Cathepsin B (Santa Cruz, Sc-13985), Cathepsin D (R&D Systems, AF1029), Cathepsin L (R&D Systems, AF1515), TMEM106B (clone 344, (104)), GAPDH (Invitrogen, AM4300)) followed by incubation with HRP-conjugated secondary antibodies, detection using ECL Plus substrate (Thermo Fisher

720

Scientific) and imaged using an Amersham ImageQuant 800 system (Cytiva). Images were quantified using the MultiGaugeV3.0 software (Fujifilm Life Science).

Lysosomal protease activity assays

725 Cells were lysed under mild conditions (50 mM Na-citrate pH 5.0, 0.8% (v/v) NP-40) for 15 min on ice before centrifugation and lysosomal protease activities performed as previously described (12). Activity assays for cathepsin B (Abnova, KA0766), cathepsin D (Abnova, KA0767) and cathepsin L (Abnova, KA0770) were performed according to the manufacturer's instructions using samples with normalized protein concentrations. Fluorescence generated by cleavage of the
730 quenched substrate was measured using a Fluoroskan Ascent FL plate reader.

ELISA-based quantification of mTrem2

For the analysis of total cellular and soluble Trem2, samples were homogenized in either high salt lysis buffer or CST lysis buffer (Cell Signaling Technologies (CST), 9803) with protease and
735 phosphatase inhibitors. Trem2 measurements were made using the Mesoscale Discovery (MSD) platform as previously described (29, 105) using a biotinylated anti-mTrem2 polyclonal antibody (R&D Systems BAF1729) as capture antibody and a sulfo-tagged detection antibody (sheep anti-mouse Trem2, AF1729 R&D Systems). MSD plates were developed using 2x MSD read buffer T, followed by detection using an MSD Meso Sector S600 reader. MSD values were converted to
740 absolute quantities of Trem2 by interpolating from a 4-parameter logistic curve fit to the mouse Trem2-His protein standard using Graphpad Prism software. For the same samples BCA protein analysis was performed and Trem2 levels were normalized using the protein concentrations.

ELISA-based quantification of mPGRN and hPGRN

745 For the analysis of total cellular and soluble PGRN in DKO mice, samples were homogenized in high salt lysis buffer with protease and phosphatase inhibitors. PGRN measurements were made using the Mesoscale Discovery (MSD) platform as previously described (106) using either a biotinylated anti-hPGRN antibody (R&D Systems, BAF2420) or anti-mPGRN antibody (R&D Systems, BAF2557) at 0.2 $\mu\text{g}/\text{mL}$ as capture antibody and for detection rabbit anti-hPGRN

750 (Thermo Fisher Scientific, 40-3400) or a rat anti-mPGRN (R&D Systems, MAB25571) antibody
at 0.25 µg/mL followed by sulfo-tagged secondary antibodies (anti-rabbit and anti-rat
respectively). MSD plates were developed using 2x MSD read buffer T, followed by detection
using an MSD Meso Sector S600 reader. MSD values were converted to absolute quantities of
PGRN by interpolating from a 6-parameter logistic curve fit to the recombinant protein standard
755 (Workbench v4 software (MSD)).

Human PGRN levels in *Grn* KO mice were measured using the DuoSet ELISA kit (R&D DY2420)
as previously described (29). Concentrations were calculated by interpolating values against an 8
point standard curve using Graphpad Prism.

760 **Neurofilament light-chain analysis**

Plasma and CSF neurofilament light chain (NfL) levels were analyzed as previously described (29)
using the Quanterix Simoa Neurofilament Light Advantage kit. Plasma was diluted 20x in sample
diluent and CSF was diluted 100x in sample diluent. Sample NfL concentrations were measured
using the NfL analysis protocol on the Quanterix SR-X instrument and interpolated against a
765 calibration curve provided with the Quanterix assay kit.

Immunofluorescence labeling of mouse brain tissue

For the analysis of DKO mouse brains, tissue was postfixed with 4% paraformaldehyde (PFA) for
24 h directly after tissue extraction, cryoprotected in 30% sucrose for 3 nights and subsequently
770 embedded in Tissue-Tek OCT cryo-embedding matrix prior to freezing the tissue on dry ice. Brain
samples were cut into 16 µm sections (CryoStar NX70 HOMVP, Thermo Fisher Scientific) and
stored at -80°C. Immunofluorescence staining was performed on sections that were adjusted to RT
for 30 min and washed with PBS to remove excess embedding matrix. Sections were transferred
to citrate buffer (0.01 M, pH 6.0) for antigen retrieval. Tissue permeabilization was performed by
775 incubating sections with 0.5% Triton-X-100 in PBS for 10 min. Blocking was performed using a
mixed blocking solution (2.5% bovine serum albumin, 2.5% fish gelatin, 2.5% fetal calf serum in
PBS). Primary antibodies (Map2 (1:500, Novusbio, NB300-213), Iba1 (1:400, Synaptic Systems,
234004), Gfap (1:500, Thermo Fisher Scientific, 13-0300) Cd68 (1:500, abcam, ab125212), p62
(1:200, MBL, PM045)) were diluted in antibody diluent (0.625% bovine serum albumin, 0.625%

780 fish gelatin, 0.625% fetal calf serum in PBS) and incubated for 24 h at 4°C, followed by incubation with fluorophore-coupled secondary antibodies (Thermo Fisher Scientific), for 1 h at RT. Afterwards, sections were incubated with DAPI (1:1000, Thermo Fisher Scientific, 62248) for 10 min and mounted with ProLong™ Gold Antifade mounting solution (Invitrogen, P36930).

For the analysis of *Grn* KO mouse brains, samples were processed as previously described (29),
785 tissue was postfixed with 4% PFA for 24 h directly after tissue perfusion and extraction, cryoprotected in 30% sucrose overnight before section at 40 µm thickness using a freezing microtome. Immunofluorescence staining was performed on free floating sections. Blocking and antibody washes were performed using a mixed blocking solution (1% BSA + 5% Normal Donkey Serum + 0.3% Triton-X-100 in PBS). Primary antibodies (Cd68 (1:500, BioRad MCA1957), Iba1
790 (1:400, Novus NB100-1028), and Gfap (1:500, Novus NBP1-05198) were used and incubated for 24 h at 4°C, followed by incubation with fluorophore-coupled secondary antibodies (Thermo Fisher Scientific), for 2-4 h at RT. Afterwards, sections were incubated with DAPI (1:5000, Thermo Fisher Scientific, 62248) for 10 min and mounted with ProLong™ Gold Antifade mounting solution (Invitrogen, P36930).

795

Immunofluorescence labeling of hiPSC cultures

Cells were fixed by replacing the culture media with 4% PFA (Thermo Fisher Scientific, J19943.K2) and incubating at 37°C, 95% humidity and 5% CO₂ for 15 min, before storage at 4°C in PBS until further processing as previously described (107). After two initial PBS washes, cells
800 were permeabilized using 0.1% Triton-X-100 in PBS, before blocking in SuperBlock™ blocking buffer (Thermo Fisher Scientific, 37515). Primary antibodies (MAP2 (1:1000, abcam, ab92434), IBA1 (1:400, Invitrogen, PA5-27436)) were diluted in SuperBlock™ and samples incubated at 4°C for 24 h followed by incubation with fluorophore-coupled secondary antibodies (Thermo Fisher Scientific) for 90 min at RT. Cells were incubated with DAPI for 10 min and mounted with
805 ProLong™ Gold Antifade mounting solution.

Image acquisition

For quantification, full brain hemispheres were imaged at 20x using a Zeiss Axio Scan.Z1 digital slide scanner or a Leica DMI-8 epifluorescence microscope with a DFC9000GT camera and a 20x

810 objective (HC PL FL L 20x/0.40 CORR PH1). Image mosaics were merged using the Leica LAS
X software suite. Analysis was completed using Zeiss Zen Blue 3.2 software or ImageJ. Image pre-
processing to eliminate illumination gradient aberrations using a difference of gaussian filters with
the CLIJ2 plugin (108) was performed. Regional ROIs were drawn, and a rolling ball thresholding
815 approach was used to determine the area of each marker relative to total regional area. 1-3 sections
were analyzed per brain and average percent coverage values were calculated across images.
Representative images were acquired on a Zeiss spinning disc microscope using a 40x/1.3 n.A. oil
immersion objective or on a Zeiss LSM800 Axio Observer 7 confocal microscope with a 63x
(63x/1.4 Oil) or a 40x (40x/1.3 Oil) objective. Post-processing was performed in ImageJ.

820 **Statistical analysis**

All non-sequencing or lipidomics data was analyzed using either a Student's t-test, one-way
analysis of variance 1555 (ANOVA), or two-way ANOVA with multiple comparisons when
indicated. Data was plotted and statistical tests were performed using GraphPad Prism. All studies
and sample analyses were performed blinded and in randomized order. Studies with multiple assays
825 were designed to be powered for the most variable analyte based on previous data. Exclusion of
mice only occurred if confounding health concerns were identified during the study. Data was only
excluded in circumstances when extreme outliers were identified (ROUT, Q = 0.5%). All heatmaps
were generated in R using the Complex Heatmap package. Data represented as mean \pm SEM or
mean \pm SD for *in vitro* and *in vivo* graphs. N is defined as the number of independent experiments
830 or biological replicates in an *in vitro* study and as the number of mice in an *in vivo* study.

Acknowledgements

We would like to thank Dr. Masugi Nishihara (Department of Veterinary Physiology, University of Tokyo) for providing the *Grn* KO founder mouse strain used at DZNE Munich and Dr. Benedikt Wefers (Taconic Biosciences) and Dr. Wolfgang Wurst (Helmholtz Center Munich) for the generation of the *Grn/Tmem106b* DKO mouse strain. We want to thank Dr. Astrid Feiten for helping with analysis of behavior experiments, Dennis Crusius for help with iPSC experiments, Ramona Rodde for mouse genotyping, Claudia Thiel for help in rotarod assessment (all Ludwig Maximilian University of Munich) and all employees of the animal facility of the DZNE Munich for animal maintenance. We thank Martin Larhammar, Mollie Jacobs, and Zach Sweeney for contributions in the early stage of the project, as well as Connie Ha, Timothy K. Earr, Hoang Nguyen, and Roni Chau for technical help. We also thank Rene Meisner for the toxicology analysis, Karen Lai, Richard Tsai and our Takeda colleagues for critical reading of the manuscript.

Funding: This work was supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy within the framework of the Munich Cluster for Systems Neurology (EXC 2145 SyNergy – ID 390857198 to CH and DP) and a Koselleck Project HA1737/16-1 (to CH), the donors of the ADR AD2019604S, a program of the BrightFocus Foundation (to DP), and Alzheimer's Association ADSF-21-831213-C (to CH and DP).

Author Contributions

Conceptualization: MR, MJS, MSK, SLD, JWJ, AC, GDP, CH

Methodology: MR, MJS, IP, GW, SR, SSD, GL, LSc, LSp, SB, TL, MS, MSK, JHS, TS, SLD, JWJ, DP, AC, GDP, CH

Fig. S1: AAV-expressed 8D3:PGRN has minimal effects on red blood cells in *Grn* KO mice. Quantification of blood cell measurements including number of red blood cells (RBC) (A), number of reticulocytes (B), mean corpuscular volume (MCV) (C) and mean corpuscular hemoglobin (MCH) (D) in 12-month-old *Grn* KO mice following 31 weeks of AAV(L):bPGRN treatment. Data is depicted as mean \pm SEM, data points represent individual samples. For statistical analysis, one-way ANOVA with Tukey's multiple comparison was performed. * $p < 0.05$, ** $p < 0.01$.

Fig. S2: AAV-mediated delivery of 8D3:PGRN does not alter endogenous PGRN levels in WT mice. (A) mPGRN levels in plasma following AAV(L):bPGRN treatment in WT and DKO mice as assessed by ELISA (n=3-7/group). (B) mPGRN levels in brain following treatment as assessed by Western blot (n=3/group). (C) Quantification of mPGRN levels in B normalized to WT (n=3/group).

Data is depicted as mean \pm SD, data points represent individual animals. For statistical analysis, one-way ANOVA with Tukey's multiple comparison was performed. ns $p > 0.05$.

Fig. S3: AAV-expressed 8D3:PGRN ameliorates behavioral abnormalities in DKO mice. (A) Representative images of 15-week-old mice 9 weeks after AAV(L):bPGRN treatment before and after flipping. **(B)** Representative images of hind limb clasping test showing 15-week-old mice 9 weeks after treatment.

Fig. S4: AAV-mediated delivery of 8D3:PGRN reduces TDP-43 pathology in DKO and Nfl in *Grn* KO mice. (A,C) Western blot showing the protein levels of TDP-43 in the high salt (A) and RIPA (B) fractions of brains of untreated and AAV(L):bPGRN-treated WT and DKO mice by using antibodies either directed against the C-terminus or the N-terminus (n=3/group). (B,D) Quantification of the protein levels in A (B) and C (D) normalized to WT (n=3/group). (E) NfL levels in plasma and CSF of *Grn* KO animals following AAV(L):bPGRN treatment. n=5-6/group. Data is depicted as mean \pm SD (B,D) or mean \pm SEM (E), data points represent individual animals. For statistical analysis, one-way ANOVA with Tukey's multiple comparison was performed. ns p > 0.05, *p < 0.05, **p < 0.01.

showing Iba1⁺ and Cd68⁺ cells (scalebar = 20 μ m). **(C)** Regional quantification of Cd68 and Iba1 in whole hemispheres (left), cortex (middle left), hippocampus (middle right) and thalamus (right). **(D)** ELISA-quantified mTrem2 levels in brain (left), liver (middle) and plasma (right) in 12-month-old *Grn* KO mice following 31 weeks of AAV(L):bPGRN treatment. n=5-6/group. Data is depicted as mean \pm SEM ns p > 0.05, *p < 0.05, **p < 0.01, ***p < 0.001, ****p < 0.0001.

Fig. S6: AAV-mediated delivery of 8D3:PGRN partially restores genetic cell type

composition within the brain. (A) Heatmap depiction of the top 785 differentially expressed genes in DKO mice and correction with AAV(L):bPGRN with a false discovery rate (FDR) < 5% and at least a 20% change comparing WT and DKO. Plotted values are log₂ transformed. (B) Expression of astrocyte (blue), microglia (green), neurons (purple) and oligodendrocyte (red) markers in the treated and untreated WT and DKO mice. (C) Heatmap depiction of the top 29 differentially expressed microglia-specific genes in DKO mice and correction with AAV(L):bPGRN with a false discovery rate (FDR) < 5% and at least a 20% change comparing WT and DKO. Plotted values are log₂ transformed. n=7/group. Data is depicted as mean ± SD. ns p > 0.05, *p < 0.05, **p < 0.01, ***p < 0.001, ****p < 0.0001.

Fig. S7: AAV-mediated delivery of 8D3:PGRN restores lipid profile of *Grn* KO mice. (A) Heatmap depiction of differentially regulated lipids in *Grn* KO mice and correction with AAV(L):bPGRN treatment. Columns represent individual animals. Plotted values are log₂ transformed. FDR cutoff: <5%, change cutoff: >20%. (B) Bar plots of treatment response of BMPs and gangliosides. n=5/group. Data is depicted as mean ± SEM. ****p < 0.0001.

Fig. S8: Generation of *TMEM106B*×*GRN* DKO hiPSC. (A) Schematic overview of the edited locus on exon 2 of the *TMEM106B* gene. Indicated are the sgRNA target sequence, the protospacer

adjacent motif (PAM), reading frame with WT and DKO amino acid sequence and Sanger sequencing traces of WT and DKO lines. **(B)** Western blot confirming loss of TMEM106B and hPGRN in edited hiPSC in comparison to WT. **(C)** Immunofluorescence images showing expression of pluripotency markers SSEA4, NANOG, TRA160 and OCT4 (scalebar = 50 μ m) in edited iPSCs. **(D)** Sanger sequencing of heterozygous SNPs on both sides of the edited locus in WT and DKO confirm that no loss of heterozygosity was induced by CRISPR editing. **(E)** Overview of the most likely off-targets as assessed using CRISPOR. Sanger sequencing of the PCR-amplified off-target sequences showed no deviation from the WT sequence. **(F)** Karyogram of DKO cell line indicating integrity of all chromosomes after editing, as assessed by molecular karyotyping.

TableS1: Summary of histopathological findings in Grn KO mice treated with AAV(L):bPGRN

Tissue	Microscopic findings			Comments
	WT	Grn KO	Grn KO AAV	
Brain	0	0	0	
Heart	0	0	0	
Lung	4	5	2	<i>Mild infiltrates in all groups</i>

The author of this thesis is one of the first authors of this manuscript.

Author contributions:

Conceptualization: AC, CH

Methodology: AC, MR, MTM, SR, KB, EW, QM, GW, AA, CK, BB, SG, AR, HR, MJS

Investigation: AC, MR, MTM, SR, KB, EW, QM, GW, AA, CK, BB, SG, AR, HR, MJS

Visualization: AC, MR, MTM, SR

Funding acquisition: AC, CH, DP

Project administration: AC, CH, SE, BB, SG, TR, DE, MJS, MSK, TL, GDP, CVB, MD, DP

Supervision: AC, CH, SE, BB, SG, TR, DE, MJS, MSK, TL, GDP, CVB, MD, DP

Writing – original draft: AC, CH, MR, MTM, SR

My author contributions in detail:

For this study, I performed and analyzed the overexpression of legumain in HeLa cells. This includes the transfection of HeLa cells, as well as the analysis by western blot and activity assays. I also performed and analyzed the media transfer experiments from HeLa overexpressing legumain to primary neurons. This includes the isolation and culturing of primary hippocampal mouse neurons, as well as their treatments with HeLa supernatants after legumain transfection, followed by analysis by western blot, activity assays and immunofluorescence. I further initiated and coordinated the collaboration with Roche, where we obtained a selective legumain inhibitor. With this inhibitor, I performed a

treatment study in hiPSC-derived microglia/neuron co-cultures, analyzing the effect of treatment on TDP-43 pathology and legumain activity by western blot and activity assays. For the overexpression of human legumain in *Grn* KO mice, I performed *i.v.* tail vein injections of the AAV. Additionally, I analyzed the PTV:PGRN-treated mouse brain samples that were generated at Denali by western blot and activity assay. For all these experiments except the legumain-AAV study, I also performed the data analysis, interpretation and visualization. I wrote parts of the initial draft of the manuscript together with AC, MTM, SR and CH and incorporated suggestions from other authors with AC and MTM.

Enhanced legumain activity links progranulin deficiency to TDP-43 pathology in frontotemporal lobar degeneration

Key words: AEP, Frontotemporal dementia, LGMN, lysosomes, microglia, neurodegeneration, progranulin, TDP-43.

Loss-of-function mutations in *GRN* are a major cause of frontotemporal lobar degeneration (FTLD) with TDP-43-positive inclusions. Progranulin (PGRN) loss leads to lysosomal dysfunction, microglial hyperactivation, and TDP-43 deposition, yet the underlying pathomechanism remains unknown. We demonstrate that PGRN slows the maturation and limits the proteolytic activity of the lysosomal protease legumain (LGMN). Accordingly, LGMN activity is strongly elevated in *Grn* knockout (ko) mice, in human induced pluripotent stem cell-derived *GRN* ko microglia, and in FTLD-*GRN* patients' brain. Secreted microglial LGMN is internalized by neurons, where it mediates pathological processing of TDP-43, which is prevented by selective LGMN inhibition. In contrast, AAV-mediated overexpression of LGMN in mouse brains promotes TDP-43 processing, the aggregation of phosphorylated TDP-43 and increases plasma neurofilament light chain (NfL), a marker for neuronal loss. Our findings identify LGMN as a link between PGRN haploinsufficiency and TDP-43 pathology in FTLD-*GRN* and suggest LGMN as a therapeutic target.

Main

Frontotemporal lobar degeneration (FTLD) is a non-curable, rare, early-onset neurodegenerative disorder¹. Up to 50% of FTLD patients develop TAR DNA binding protein 43 (TDP-43) pathology, which is characterized by aberrant TDP-43 processing, cytosolic deposition, abnormal phosphorylation and nuclear clearance^{2,3}. Heterozygous loss-of-function (LOF) mutations in the *GRN* gene are a major cause of FTLD (FTLD-*GRN*) with TDP-43 pathology^{4,5}, whereas homozygous LOF mutations result in neuronal ceroid lipofuscinosis (NCL)^{6,7}, a lysosomal storage disorder. In the brain, progranulin (PGRN), a secreted growth factor-like protein, is critical for neuronal survival⁸ and diminishes inflammatory processes and hyperactivation of microglia upon CNS damage⁹. As a result, loss of PGRN in mice leads to inflammation and the transition of microglia to a disease associated microglia (DAM) population¹⁰⁻¹². Microglial dysregulation upon PGRN loss may be associated with its function within lysosomes¹³. NCL cases caused by loss of PGRN and PGRN-deficient mouse models

exhibit multiple endo-lysosomal and autophagic phenotypes, such as dysregulation of lysosomal proteases and pH¹⁴⁻²⁰, lipid dyshomeostasis, and lipofuscin accumulation^{13,16,21-25}. PGRN is either secreted or transported to lysosomes *via* multiple pathways, including sortilin and prosaposin/cation-independent mannose-6-phosphate receptor²⁶. Upon increased acidification of the endo-lysosomal pathway, PGRN is proteolytically processed into granulin peptides by the lysosomal protease legumain (LGMN), also known as asparagine endopeptidase (AEP), and probably by various cathepsins, including cathepsin B and L²⁷⁻²⁹. An essential role of granulins in lysosomes is suggested, since lysosomal dysfunction caused by PGRN deficiency is ameliorated by granulin peptides³⁰. Despite intense research, both the lysosomal function of PGRN / granulins and the mechanistic link between PGRN deficiency and TDP-43 aggregation remain unclear. A spatial paradox, namely PGRN expression primarily in microglia and TDP-43 pathology in neurons, makes the understanding of the link between PGRN loss and TDP-43 pathology even more challenging.

We have previously shown that loss of PGRN causes lysosomal dysfunction with altered cathepsin maturation¹⁸. To establish a functional link between PGRN deficiency and TDP-43 pathology, we hypothesize that lysosomal dysfunction contributes to disease-associated proteolytic TDP-43 processing. We therefore searched for a protease which plays a key role in processing of TDP-43 and lysosomal cathepsins. LGMN, a caspase-like cysteine protease of the C13 peptidase family emerged as a prime candidate³¹, since it is involved in the proteolytic turnover of various cathepsins^{32,33} and capable of cleaving TDP-43 *in vitro*³⁴. Here, we provide a mechanistic link between PGRN deficiency and TDP-43 pathology *via* dysregulation of LGMN.

Results

PGRN deficiency results in elevated LGMN maturation and activity

To test our hypothesis, we investigated LGMN expression and activity in various model systems and in brain material from FTLD-GRN patients. Mature LGMN and its proteolytic activity were strongly elevated in *Grn* ko MEF compared to wt MEF (Fig. 1a,b). In line with that, knockdown of LGMN blunts the previously described increased maturation and accumulation of the heavy chain of cathepsins D and L in the *Grn* ko MEF (Extended Data Fig. 1a–c)¹⁸. *LGMN* ko mice further proved that LGMN is required for the generation of the heavy chain form of cathepsin L³⁵ and cathepsin D in mice

(Extended Data Fig. 1d). Moreover, elevated levels of mature LGMN were detected in the brain tissue of 6-month-old *Grn* ko mice (Fig. 1c) and increased proteolytic activity of LGMN was observed in all ages investigated between 3 and 24 months (Fig. 1d), indicating that LGMN dysfunction might be a driver of the disease and not a response. Increased LGMN expression and activity were not a result of transcriptional changes (Fig. 1e), suggesting posttranscriptional regulatory mechanisms. To test whether the increase in LGMN maturation and activity is directly caused by the loss of PGRN, we reintroduced PGRN in *Grn* ko MEF and *Grn* ko mice (Extended Data Fig. 2a-e). Restoration of PGRN in *Grn* ko MEF by stable transfection reduced mature LGMN and completely normalized LGMN hyperactivity (Extended Data Fig. 2a-b). To reintroduce PGRN *in vivo*, we used the previously described protein transport vehicle (PTV):PGRN, which shows enhanced brain penetrance due to its ability to bind to the transferrin receptor (TfR), to restore brain PGRN levels in *Grn* ko mice expressing chimeric humanized TfR (*Grn* ko; *TfR* ki) (Extended Data Fig. 2c)¹⁶. PTV:PGRN reduced maturation and activity of LGMN over time (Extended Data Fig. 2d-e). Thus, PGRN appears to directly affect LGMN maturation and consequently its proteolytic activity.

In the brain, PGRN is predominantly expressed by microglia^{11,18}. In contrast, pathological TDP-43 inclusions observed in FTLD or amyotrophic lateral sclerosis (ALS) are mainly localized in neurons and are less abundant in glial cells^{2,3}. Thus, we next investigated cell type-specific expression of LGMN. LGMN and PGRN were both strongly enriched in acutely isolated microglia (Fig. 1f; Extended Data Fig. 3). Moreover, microglia showed efficient LGMN maturation as well as the highest LGMN activity of all cell types investigated (Fig. 1f-g; Extended Data Fig. 3). Even though LGMN expression in neurons and astrocytes was much lower than in microglia, the relative change in LGMN activity between PGRN deficient and wt cells was highest in neurons with a 3-fold increase in *Grn* ko (Fig. 1g). In contrast to the LGMN activity, *Lgmn* mRNA levels were not increased in acutely isolated microglia (Fig. 1h), supporting the conclusion that LGMN is regulated at a posttranscriptional level. In addition, in primary cultures of *Grn* ko microglia LGMN activity was twice as high as in wt controls, mirroring the results obtained from the acutely isolated microglia (Fig. 1i). To investigate whether elevated LGMN levels are disease relevant, we assessed LGMN maturation and activity in the frontal cortex (Brodmann area 9 and 10) of patients suffering from FTLD-GRN (Extended Data Table 1). In line with our findings

in the model systems described above, we observed increased levels, maturation and proteolytic activity of LGMN in patient brains relative to age matched non-diseased controls (Fig. 1j,k).

Fig. 1: PGRN deficiency leads to enhanced LGMN maturation and elevated activity.

a, Representative immunoblots of mouse embryonic fibroblasts (MEF), isolated from wild-type (wt) and granulin knockout (*Gm* ko) mice, probed for progranulin (PGRN), legumain (LGMN), and calnexin as loading control. MEF are either non- (-), control- (*ctrl*) or *Lgmn* siRNA-transfected. Quantification of LGMN expression normalized to non-transfected wt levels (n=4). **b**, *In vitro* LGMN activity of non- (-), mock, *ctrl* and *Lgmn* siRNA-transfected *Gm* ko MEF

normalized to non-transfected wt MEF (n=4). **c**, Representative immunoblot for LGMN in total brain homogenates of 6-month-old wt and *Grn* ko mice. Proform (LGMN_p), mature form (LGMN_m), and non-specific band (*) are indicated, β -actin verified equal loading. Quantification of the immunoblot signals normalized to wt (n=3 mice per genotype). **d**, *In vitro* LGMN activity of brain homogenates from 3-, 6-, 12-13-, and 20-24-month-old wt and *Grn* ko mice (n=4-6 per genotype and age group). **e**, Total brain mRNA of 3-, 6-, 12-13-, and 20-24-month-old mice normalized to wt (n=4-5). **f**, Representative immunoblot for LGMN in MACS-sorted microglia-, astrocyte- and neuron-enriched brain cell fractions of 4-5-month-old wt and *Grn* ko mice. LGMN_p and LGMN_m are indicated, calnexin verified equal loading for each fraction. **g**, Microglia-, astrocyte- and neuron-enriched fractions from 4-5-month-old *Grn* ko and wt mice analyzed for LGMN activity either normalized to wt microglia or wt of the respective cell type (insert) (n=3 mice per cell type and genotype). **h**, *Lgmn* mRNA levels of microglia isolated from 6-month-old wt and *Grn* ko mice normalized to wt (n=5). **i**, LGMN *in vitro* activity in lysates of cultured primary mouse microglia (n=3 mice per genotype). **j**, **k**, LGMN expression (**j**) and activity (**k**) analyzed in brain lysates of frontal cortex from FTLD/*GRN* patients and pathology-negative control cases (see Extended Data Table 1). LGMN_p and LGMN_m are quantified in the immunoblot and normalized to the mean signal of control cases (**j**).

Data are mean \pm s.d. of biologically independent experiments; unpaired two-tailed t-test: ns not significant; * P <0.05, ** P <0.01, *** P <0.001, **** P <0.0001. P values and statistical source data are provided.

PGRN slows LGMN auto-activation

Next, we investigated whether PGRN directly affects LGMN catalytic activity or interferes with its proteolytic activation. With decreasing pH during lysosome maturation, LGMN is autoproteolytically activated in multiple steps and processed to its final mature form of approximately 43 kDa by unknown proteases (Fig. 2a)³⁶. Autocatalytic *in vitro* maturation of the pro-form of LGMN (pro-LGMN) to an intermediate active form has been previously shown to be facilitated at an acidic pH³¹. To investigate whether PGRN directly affects LGMN activity, we measured the *in vitro* activity of autocatalytically pre-activated recombinant (r) LGMN in the presence and absence of rPGRN. PGRN did not affect the catalytic activity of rLGMN (Fig. 2b). Based on the increased LGMN maturation in various PGRN deficient model systems (Fig. 1), we next investigated whether the presence of rPGRN affects maturation of rLGMN.

Fig. 2: PGRN modulates LGMN activation and is proteolytically processed by LGMN.

a, Schematic representation of pH-dependent auto- and not auto-catalytic LGMN maturation. N- and C-terminal pro-peptides (p1-p3) and the mature chain (c) with the active site residues (blue stars) are specified. Proform (LGMN_p), intermediate-form (LGMN_i) and mature-form (LGMN_m) are indicated. **b**, **c**, Activity analysis of *in vitro* auto-catalytically matured recombinant (r) LGMN incubated for 4 h at acidic pH. Either rPGRN or elastase-digested PGRN were added after (b) or before the 4 h activation step (c) (n=3). **d**, PGRN digest with elastase controlled by immunoblotting. **e**, **f**, Activation of rLGMN with/without rPGRN at acidic pH for indicated time points, monitored by immunoblotting. Quantification of the relative LGMN_i level (% of total LGMN) (e) or activity (f) for each timepoint (n=3). **g**, LGMN activity after 2 h incubation with different concentrations of rPGRN at pH 4. The IC₅₀ was calculated using a non-linear curve fit, 95% confidence intervals (CI) are indicated (n=3). **h**, Immunoblot analysis of rPGRN turnover and granulin peptide generation by rLGMN. Stars indicate rLGMN independent bands. Data are mean ± s.d. of independent technical replicates, unpaired two-tailed t-test: ns,

not significant; * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, **** $P < 0.0001$. P values and statistical source data are provided.

Strikingly, rLGMN activity was reduced by more than 50 % when rPGRN was added to pro-rLGMN during the activation step at acidic pH 4 (Fig. 2c), while elastase-digested rPGRN did not reduce rLGMN activation (Fig. 2c,d), suggesting that rPGRN, but not granulins, regulate the maturation of rLGMN. Autocatalytic maturation of pro-rLGMN was then monitored longitudinally at pH 4.0 with and without rPGRN. Proteolytic *in vitro* maturation and enzymatic activation of rLGMN under acidic conditions was significantly slowed in the presence of rPGRN (Fig. 2e,f). Moreover, rPGRN reduced autocatalytic activation of rLGMN in a dose-dependent manner with an IC_{50} of 39.28 nM (Fig. 2g). However, after full autocatalytic maturation (Fig. 2e), the catalytic activity of rLGMN was identical in the presence and absence of rPGRN (Fig. 2f). Thus, PGRN does not affect the catalytic activity of LGMN *per se*, but rather slows its autocatalytic maturation. Intriguingly, as suggested before²⁹, rLGMN efficiently generates granulin peptides *in vitro* (Fig. 2h). After 8 h of co-incubation of rPGRN with rLGMN, full length rPGRN was completely converted into single or multiple granulin peptides. At this time point also full conversion of rLGMN to the intermediate form was observed (Fig. 2e), further indicating that full length PGRN is needed to slow LGMN activation and that LGMN regulates its own maturation by processing of PGRN in a negative feedback loop. *In vivo*, the interaction of LGMN with PGRN is supported by reduced generation of granulins in *Lgmn* ko mice. Granulin peptides are readily detected within purified liver lysosomes of wt mice, but are substantially reduced in *Lgmn* ko mice (Extended Data Fig. 4a,b). Thus, LGMN regulates its own maturation by processing of PGRN in a negative feedback loop.

Increased LGMN activity promotes pathological processing of TDP-43

Since TDP-43 is known to undergo pathological proteolytic processing^{2,37,38} and contains several potential cleavage sites for LGMN³⁴ (Fig. 3a), we investigated if the lack of PGRN affects processing of TDP-43 *via* enhanced LGMN activity. In *Grn* ko MEF we observed a reduction of full-length TDP-43 accompanied by the enhanced formation of TDP-43 fragments (TDP-43_F) which were enriched in the urea solubilized fraction (Fig. 3b). Furthermore, C-terminal fragments of TDP-43 (TDP-43_{CTF}) with an approximate molecular weight of 25 kDa, reminiscent of those observed in FTLD cases³⁴, were observed in lysates of *Grn* ko MEF (Fig. 3b,c). Abnormal proteolytic

processing of TDP-43 was completely blocked upon knockdown of LGMN in *Grn* ko MEF (Fig. 3b,c), proving that disease-defining TDP-43 fragments are generated in a LGMN-dependent manner. Moreover, even in the presence of PGRN, reduction of LGMN was sufficient to reduce TDP-43 processing (Fig. 3b). Immunofluorescence staining of TDP-43 revealed significant cytoplasmic mis-localization of TDP-43 in *Grn* ko MEF (Fig. 3d, upper panels). MEF *Grn* ko show enhanced co-localization of TDP-43 with LGMN- and LAMP1-positive compartments, indicating that TDP-43 processing by LGMN occurs in the lysosome (Fig. 3d, lower panels).

Taken together, our findings suggest that reduced PGRN results in enhanced LGMN activation, which in turn mediates pathological processing and mis-localization of TDP-43.

Fig. 3: Enhanced LGMN activity results in accelerated TDP-43 processing.

a, Schematic representation of the TDP-43 protein indicates the nuclear localization sequence (NLS, green), the RNA-recognition motifs (RRM1 / 2, blue), and the G-, Q-, N-rich hnRNP-interacting domains (red). Epitopes of different N-terminal (NT) and C-terminal (CT) antibodies

are indicated. Confirmed LGMN cleavage sites (black arrows) and putative fragments are indicated below. Red arrows indicate LGMN cleaved fragments identified in patient material (Herskowitz *et al*, 2012; Kametani *et al*, 2016). **b**, Immunoblot analysis of TDP-43, TDP-43 fragments (TDP43_F) and C-terminal fragments (TDP43_{CTF}) in MEF *Grn* wt and ko with and without *Lgmn* siRNA-mediated knockdown. **c**, Quantification of TDP-43 processing; holoprotein (48 kDa) and fragments (45 kDa, 40 kDa and 38 kDa) were normalized to total TDP-43 (n=4). **d**, Immunofluorescence staining of the lysosomal protein LAMP1 (deep red), LGMN (orange), TDP-43 (green) and nuclear DAPI staining (blue) of *Grn* wt and ko MEF (top panels scale-bar 10 μ m, lower panels 20 μ m). Arrowheads indicate co-localization of LAMP1, LGMN and TDP-43, encircled is a cytoplasmic DAPI, LGMN and TDP-43 positive area. Quantification of % cytoplasmic vs. total TDP-43. Data are mean \pm s.d. (n=48-69 cells / genotype from 6-8 images), unpaired two-tailed t-test, **** P <0.0001. P values and statistical source data are provided

Shuttling of LGMN from microglia to neurons

TDP-43 deposits are predominantly found in neurons, however compared to microglia, neurons express substantially less PGRN and LGMN and therefore show much less LGMN activity (Fig. 1f,g, Extended Data Fig. 3). Since pro-LGMN was found to be secreted in peripheral immune cells³⁶, we hypothesized that PGRN-deficient hyperactivated microglia also release pro-LGMN, which could be internalized by neurons, where it then mediates pathological TDP-43 processing. To provide evidence that catalytically inactive pro-LGMN can be taken up and activated by neurons, we incubated primary mouse hippocampal neurons with conditioned media from wt, inactive mutant (mt) LGMN-, or mock-transfected HeLa cells (Fig. 4a). Robust levels of overexpressed wt and mt LGMN were detected in HeLa cells. Autocatalytic processing occurred in wt, but was altered in mt LGMN expressing cells, suggesting bimolecular processing by endogenous LGMN or alternative processing (Fig. 4b)^{39,40}. Upon transfection, conditioned media contained significant amounts of secreted wt or mt pro-LGMN (Fig. 4c). Only secreted wt LGMN was autocatalytically activated upon incubation under acidic conditions while no activity was observed in conditioned media of mt LGMN or non-transfected HeLa cells (Fig. 4d). Both, wt and mt LGMN were internalized and either autocatalytically or alternatively processed in primary neurons (Fig. 4e). Noticeably, processed mt LGMN accumulated in lysates (Fig. 4e). Only neurons incubated with wt LGMN-containing conditioned media show increased LGMN activity (Fig. 4f). Strikingly, we observed enhanced TDP-43 processing relative

to total TDP-43 levels and even the formation of pathological TDP-43_{CTF} upon uptake of wt LGMN, but not of the catalytically inactive variant (Fig. 4g). This demonstrates that proteolytically active LGMN is sufficient to generate disease-relevant TDP-43 fragments and that neurons can internalize and activate LGMN.

Fig. 4: LGMN internalized by neurons results in accelerated TDP-43 processing.

a, Schematic representation of the media transfer experiment. HeLa cells were transfected with wt mouse LGMN, the proteolytically inactive LGMN C191A variant (mt) or mock (-) and 25% conditioned media supplemented to primary hippocampal mouse neurons for 24 h. **(b,c)**, LGMN expression (LGMN_p, LGMN_i, and LGMN_m) **(b)** and secretion of LGMN_p **(c)** by HeLa cells was verified by immunoblotting (n=3 independent experiments). **(c,d)** To monitor autocatalytic processing of LGMN, conditioned media was incubated at pH 7 or pH 4 for 4 h. **d**, LGMN activity of conditioned media incubated at pH 7 and pH 4 (n=3 independent experiments). **(e-g)**, Primary neurons were analyzed after 24 h incubation with conditioned media. Presence of the LGMN proform was confirmed in culture media **(e)**. LGMN uptake by neurons **(e)** and TDP-

43 processing (**g**) in neuron lysates was detected by immunoblot and activity assay (**f**) (n=3 independent experiments). TDP-43 processing was quantified as percentage of holoprotein or fragment of total TDP-43 level for each treatment condition (n=3 independent experiments). Statistical significance for the activity assay (**f**) and TDP-43 processing (**g**) was determined by one-way ANOVA and Tukey's post-hoc test: **** $P < 0.0001$. P values and statistical source data are provided.

To provide evidence for a pathological link between PGRN reduction, LGMN activation, and enhanced TDP-43 processing in a human disease-relevant system, we generated human iPSC lacking PGRN (*GRN* ko iPSC)²² and differentiated them into human induced pluripotent stem cell-derived microglia (hiMGL) and neurons (hiNE). *GRN* ko hiMGL showed a 3-4-fold increased expression and activity of LGMN compared to wt hiMGL (Fig. 5a,b) but only a 1.5-fold increase of *LGMN* mRNA levels (Fig. 5c). Thus, the difference in LGMN mRNA levels between wt and *GRN* ko hiMGL was less pronounced than on LGMN protein or activity levels, further supporting a post-transcriptional regulation of LGMN activity upon PGRN deficiency. In line with our findings in mice (Fig. 1f,g), hiNE had almost no LGMN protein expression or activity (Fig. 5a,b) and showed lower transcript levels than hiMGL (Fig. 5c). Furthermore, *GRN* ko hiNE did not show an increase of LGMN activity in contrast to *Gm* ko mouse neurons (Fig. 1g). To investigate a potential cross-talk between microglia and neurons upon PGRN deficiency, we co-cultured *GRN* wt hiNE with either *GRN* wt or ko hiMGL (Fig. 5d). In co-cultures of wt hiNE with *GRN* ko hiMGL, we observed increased mature and active LGMN in lysates (Fig. 5f,g). As a consequence, co-culture of *GRN* ko hiMGL with *GRN* wt hiNE showed enhanced TDP-43 processing, indicated by reduced TDP-43 full length and enhanced TDP-43 fragments (Fig. 5h). To investigate if TDP-43 processing in the co-culture occurs predominantly within neurons, we selectively blocked neuronal LGMN activity by AAV9 (AAV-hSyn-Cst7) mediated neuronal expression of cystatin F (CSTF) prior to co-culturing with hiMGL (Fig. 5d). CSTF and CSTC are brain expressed^{41,42} effective inhibitors of LGMN (Extended Data Fig. 5a-c) and other cysteine-proteases⁴³. Since CSTF showed stronger inhibitory effects in cell culture, we decided to use AAV-hSyn-Cst7. Immunofluorescence confirmed neuronal CSTF expression (Fig. 5e), which resulted in reduced LGMN maturation and strongly reduced activity (Fig. 5f,g). Furthermore, as a consequence of the inhibition of LGMN activity, TDP-43 processing was also reduced to levels seen in wt co-culture (Fig. 5h).

Fig. 5: Elevated LGMN maturation and activity in human induced pluripotent stem cells (hiPSC)-derived microglia results in enhanced TDP-43 processing.

a, Representative immunoblot for LGMN, TDP-43, IBA1, TUJ1, and β -actin of *GRN* wt and ko hiPSC-derived microglia (hiMGL) or neurons (hiNE). LGMN_p, LGMN_m, full-length TDP-43, and TDP-43 fragments (TDP-43_f) are indicated. Quantification of LGMN_m from the immunoblot shown as mean normalized to wt hiMGL \pm s.d. (n=3). **b**, *In vitro* LGMN activity of lysates from monocultured wt and *GRN* ko hiMGL and hiNE; mean normalized to wt hiMGL \pm s.d. (n=3). **c**, qPCR of *LGMN* mRNA expression in wt and *GRN*-deficient (*GRN* ko) hiMGL or hiNE normalized to wt hiMGL, mean \pm s.d. (n=3). **D**, Scheme for **e-i**: 3-week co-culture of wt hiNE with *GRN* wt hiMGL, ko hiMGL, or ko hiMGL and AAV-Cst7 (cystatin F expressing (CSTF)) transduction. **e**, Immunofluorescence of CSTF (yellow), neurons (MAP2, magenta), and microglia (IBA1, white) with nuclear staining (DAPI, blue) upon AAV transduction (scale bar 15 μ m). Quantification of CSTF area normalized over MAP2 area (hiNE) or IBA1 area (hiMGL). Data are mean \pm s.d. of image replicates (n=9). **f**, Immunoblotting of LGMN, CSTF, and β -actin to verify equal loading. Quantification of LGMN_m over total LGMN; mean normalized to wt hiMGL co-culture \pm s.d. (n=3). **g**, LGMN activity normalized to hiNE co-cultured with wt hiMGL shown as mean \pm s.d. (n=3). **h**, Immunoblotting of TDP-43, using N-terminal (NT-ab_{long}) or C-terminal (CT-ab_{long}) anti-TDP-43 antibodies, and β -actin. Quantification of indicated TDP-43 fragments (TDP-43_f) and TDP-43 holoprotein for both antibodies; mean normalized to wt hiMGL co-culture (n=2). **i**, ELISA of LGMN detected in the media; mean normalized to wt hiMGL co-culture \pm s.d. (n=3). **j**, Scheme for **(k)**; monocultured *GRN* wt hiNE treated for 24 h with conditioned media from either 3 weeks *GRN* wt hiNE and wt hiMGL co-cultures or *GRN* wt hiNE and ko hiMGL co-cultures. **k**, LGMN activity of treated monocultured *GRN* wt hiNE, normalized to *GRN* wt hiNE treated with conditioned media from wt co-cultures (n=2). Statistical significance was determined using one-way ANOVA and Tukey's post hoc test: ns, not significant; * P <0.05, ** P <0.01, *** P <0.001, **** P <0.0001. P values and statistical source data are provided.

To investigate potential shuttling of LGMN from microglia to neurons, we initially investigated whether LGMN can be secreted and found enhanced LGMN secretion in *GRN* ko hiMGL compared to wt hiMGL both co-cultured with wt hiNE (Fig. 5i). Conditioned media from these co-cultures were added to *GRN* wt hiNE monocultures (Fig. 5j). Transfer of conditioned media derived from co-cultured ko hiMGL and wt hiNE led to increased LGMN proteolytic activity in lysates of mono-cultured wt hiNE (Fig. 5j,k). This indicates that human neurons can internalize secreted LGMN further supporting our findings that secreted LGMN from microglia can lead to enhanced TDP-43 processing in neurons.

To further validate the unique role of microglia-derived LGMN in TDP-43 processing, we treated the co-culture with a highly selective small molecule LGMN inhibitor (Extended Data Fig. 6). Upon three weeks of treatment, full-length TDP-43 was increased and TDP-43 fragments were significantly reduced. The remaining TDP-43 processing product of slightly higher molecular weight appears to be generated in a LGMN independent pathway (Fig. 6a,b). Pro-LGMN and mature LGMN were both strongly increased upon inhibitor treatment (Fig. 6a,c). Together with an approximately 90% reduction of the proteolytic activity (Fig. 6d), this suggests reduced self-degradation of LGMN. Taken together, these findings indicate that ko hiMGL release LGMN, which is taken up by neurons, where it then mediates pathological processing of TDP-43.

Fig. 6: Inhibition of LGMN activity diminishes TDP-43 processing.

P values and statistical source data are provided.

LGMN overexpression in mice results in TDP-43 pathology and motor deficits

As inhibition of LGMN activity in neurons reduced pathological processing of TDP-43, we assumed that TDP-43 pathology could be conversely enhanced *in vivo* by overexpressing LGMN. To prove if increased hLGMN expression in the brain is sufficient to induce FTLD-related pathology, 6-7-month-old *Grn* ko mice were treated *via* tail vein injection with AAV-PhP.eB-CAG-hLGMN, a serotype that was shown to have high brain penetrance as well as transduction of neurons and astrocytes⁴⁴. Three months post injection, we observed substantial overexpression of hLGMN (Fig. 7a) as well as a 13-fold increase of LGMN activity in total brain lysates (Fig. 7b). hLGMN was expressed in all brain areas (Extended Data Fig. 7a). hLGMN expression was predominantly found in neurons, and to a lesser extent in astrocytes and microglia (Extended Data Fig. 7b). In line with our *ex vivo* findings, upon hLGMN overexpression in *Grn* ko mice, we detected enhanced generation of TDP-43 fragments (Fig. 7c) and a strong accumulation of insoluble abnormally phosphorylated TDP-43 (pTDP-43) (Fig. 7c). Abnormal processing and pathological phosphorylation of TDP-43 was accompanied by motor deficits as shown by increased hind limb clasping (Fig. 7d) as well as progressing deficits in rotarod performance over time (Fig. 7e). These phenotypes resembled the phenotypes observed in the previously described *Tmem106b* ko/ *Grn* ko FTLD model⁴⁵, suggesting that LGMN overexpression in *Grn* ko can induce an FTLD-like pathology. Finally, LGMN overexpression led to a 10-fold increase in plasma neurofilament light chain (NfL) (Fig. 7f), a biomarker for neuronal damage also used in clinical studies^{46,47}. Taken together, these results suggest that LGMN is a main driver of TDP-43 pathology *in vivo*.

Fig. 7: Overexpression of hLGMN in *Grn* ko mice leads to TDP-43 pathology, motor deficits and increased plasma NfL levels.

a, Representative immunoblots for total LGMN and human LGMN (hLGMN) in total brain homogenate (NP40) of *Grn* KO mice, three months p.i. and age-matched non-injected controls, GAPDH verified equal loading. LGMN expression is quantified and normalized to *Grn* ko (n=3 mice per condition, mean ± s.d.) **b**, *In vitro* LGMN activity assay of total brain homogenate of AAV-injected *Grn* ko mice and age-matched non-injected controls (n=6 mice per condition, mean ± s.d.) **c**, Representative immunoblot of TDP-43 in the RIPA soluble fraction of total brain lysates and pTDP-43 in the urea-soluble fraction, GAPDH verified equal loading. For quantification of TDP-43 processing in the RIPA fraction, the signal of indicated TDP-43 fragments was normalized to the total TDP-43 signal (n=6 mice per condition, mean ± s.d., multiple t-tests with FDR correction). pTDP-43 accumulation in the urea fraction was quantified and normalized to *Grn* ko (n=6 mice per condition, mean ± s.d.) **d**, Representative images show assessment of hind-limb clasping phenotype in hLGMN overexpressing mice and age-matched non-injected *Grn* ko mice (n=6 mice per condition). The clasping phenotype was quantified (n=6 mice per condition, mean ± s.e.m.) **e**, Longitudinal rotarod performance of *Grn* ko mice overexpressing hLGMN and age-matched controls (n=6 for *Grn* ko + hLGMN, n=6 for *Grn* ko control mice, mean ± s.e.m., multiple t-tests with FDR correction). **f**, Plasma NfL levels were measured before injection, 1.5 months p.i. and terminally. (n=6, mean ± s.d.)

Unpaired two-tailed Student t-test or multiple t-tests with FDR correction, if indicated, were used to assign significance (two-stage step-up, Benjamini, Krieger and Yekutieli): ns, not significant; * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, **** $P < 0.0001$. P values and statistical source data are provided.

Discussion

Our findings demonstrate that enhanced LGMN activity provides a direct link between *GRN* haploinsufficiency and TDP-43 pathology. In various model systems, including two independent PGRN-deficient mouse lines, MEF, primary mouse- and hiPSC-derived microglia, and finally FTLD-*GRN* patient brains, we consistently found elevated LGMN maturation and activity. Upon co-incubation of LGMN and PGRN *in vitro*, we observed that PGRN, but not granulin peptides, delays LGMN maturation in a dose-dependent manner. Thus, PGRN slows LGMN maturation, presumably in a chaperone-like manner during trafficking to lysosomes. The inhibitory effect is balanced by LGMN itself, as it hydrolyses PGRN into non-inhibitory granulin peptides. We found that granulin peptides are reduced in *Lgmn* ko mice, thus LGMN is involved in granulin peptide generation *in vivo*. This is further supported by recent *in vitro* data by Mohan et al., who investigated the role of various lysosomal proteases in the differential processing of PGRN²⁹.

In addition, pathologically enhanced LGMN activity leads to increased processing of lysosomal cathepsins, which, consistent with previous findings^{15,18,48}, may result in dysregulation and malfunction of microglial lysosomes. Considering the potential of several lysosomal cathepsins to process PGRN as well^{27-29,49}, this could further accelerate the pathology. Based on our findings that both, knockdown of LGMN or selective inhibition of LGMN activity ameliorates pathological TDP-43 processing, whereas overexpression accelerates TDP-43 pathology, LGMN might be a main driver of FTLD-*GRN* pathology. Fragment formation is disease relevant, since proteolytically cleaved TDP-43 fragments are not only enriched in TDP-43 deposits, but such fragments are also known to be required for seeding and spreading of pathological TDP-43⁵⁰. A contribution of other proteases activated by LGMN cannot be excluded though, as the overexpression of the more general protease inhibitor CSTF showed a stronger rescue than the selective small molecule LGMN inhibitor in our hiPSC co-culture system.

Strikingly, overexpression of LGMN in *Grn* ko mice caused a severe worsening of disease phenotypes, including processing, phosphorylation and aggregation of TDP-43. Similar effects of overexpressed LGMN have been proposed for tau processing and phosphorylation in Alzheimer's disease^{51,52}. Phosphorylation of tau might be affected by elevated LGMN levels which results in reduced protein phosphatase 2a (PP2A) stability and as a consequence in hyperphosphorylated tau⁵¹. Whether this mechanism plays a role for TDP-43 phosphorylation needs to be further investigated. In addition, in *Grn* ko mice, overexpressed LGMN resulted in increased plasma NfL levels and worsened rotarod performance. Elevated NfL levels in serum and CSF of FTLD patients correlate with disease severity and brain atrophy, with particular high levels in symptomatic FTLD-GRN patients^{53,54}. TDP-43 pathology results in motor deficits in amyotrophic lateral sclerosis, but also FTLD and specifically FTLD-GRN patients can present with motor neuron disease-like syndromes⁵⁵. Since TDP-43 cleavage removes the nuclear localization signal from the C-terminal fragments, it will further enhance cytoplasmic accumulation and aggregation of TDP-43. LGMN secretion has already been described in the periphery³⁶. Here, LGMN is mainly expressed by immune cells and upregulated upon stress or in tumor microenvironment. In these conditions its pro-form was also found to be secreted³⁶. The secretion of LGMN by activated microglia and further functional consequences need to be studied in more detail in the future. Together, our findings strongly suggest that the pro-LGMN is released by PGRN deficient microglia and internalized by neurons, where it is activated and capable of processing TDP-43, thus resolving the spatial paradox of the differential expression of LGMN and PGRN predominantly in microglia, and TDP-43 pathology primarily occurring in neurons³ (Fig. 8). In which cellular compartment LGMN gains access to TDP-43 remains to be discovered. To reach cytoplasmic TDP-43 mature LGMN might be released by damaged lysosomes¹⁶. Although active LGMN is unstable at the neutral pH of the cytosol, it might be stabilized by active center interacting proteins³⁶. One could speculate that re-activation occurs by release of the binding partner in an acidic microenvironment. A more likely mechanism might be the direction of cytoplasmic TDP-43 towards autophagic degradation^{56,57} and cleavage by LGMN in autolysosomes. TDP-43 fragments might then escape damaged, leaky lysosomes¹⁶ and accumulate in the cytoplasm.

PGRN-deficiency can cause microglial hyperactivation¹⁰⁻¹² and triggers the complement cascade⁵⁸ resulting in neuronal loss. How aberrantly elevated LGMN

activity is linked to these processes remains to be investigated. As FTL-*GRN* patients also present with co-pathology of other LGMN substrates, namely tau and α -synuclein^{52,59,60}, it is conceivable that their accumulation and deposition may also be facilitated by aberrantly enhanced LGMN activity. In addition, LGMN activity was also found to be upregulated in the brains of patients with other neurodegenerative diseases, such as Alzheimer's and Parkinson's disease^{52,61}. Monitoring LGMN activity in patient brains or the increase of LGMN specific cleavage products in the CSF could be useful biomarkers in the future to monitor disease progression and lysosomal dysfunction. Finally, since TDP-43 pathology and lysosomal dysfunction co-exist in other neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, limbic-predominant age-related TDP-43 encephalopathy (LATE), Lewy Body dementia and hippocampal sclerosis, our findings may reveal a disease overarching pathway, which could be modulated by LGMN inhibitors⁶²⁻⁶⁶.

Fig. 8: Increased legumain activity caused by progranulin deficiency drives TDP-43 pathology.

Suggested pathomechanism: In homeostasis, PGRN slows the maturation of LGMN, which is regulated in a negative feed-back loop *via* processing of PGRN into single granulins by LGMN. Upon PGRN loss-of-function, lysosomal function is impaired and microglia become hyperactivated. In this context, LGMN is not regulated by PGRN anymore and its protein levels and activity increase. The pro-form of LGMN is secreted by activated microglia and taken up by neurons (mechanism unknown), where it hyperprocesses TDP-43 and thereby drives TDP-43 pathology.

Methods

Data reporting

No statistical methods were used to predetermine sample size. The investigators were not blinded to allocation during experiments and outcome assessment, except for animal motor function assessment tests.

Ethical approval

All the work involving human tissues or mice was carried out in accordance with the Code of Ethics of the World Medical Association (Declaration of Helsinki). The use of human brain material was approved by the local ethic commission of the Ludwig-Maximilian's-University, Munich. All animal experiments were performed in compliance with the national guidelines for animal protection in Germany and with the approval of the regional animal committee (Regierung von Oberbayern) directed by a veterinarian. Mice were kept in small groups under standard housing conditions at constant temperature of $21 \pm 2^\circ\text{C}$, on a 12 h light / dark cycle, providing standard pellet food and water *ad libitum*. At Denali Therapeutics Inc. all mouse procedures adhered to regulations and protocols approved by Denali Therapeutics Institutional Animal Care and Use Committee. Mice were housed under a 12 h light / dark cycle and group housed when possible.

Experimental mouse models

The *Grn* ko mouse line was provided by Dr. M. Nishihara (Department of Veterinary Physiology, The University of Tokyo)⁶⁷, backcrossed to the C57BL/6J strain and published before^{10,17,18,22,45}. Animal ages / sexes for each experiment are indicated in the source data tables.

Overexpression of hLG MN in *Grn* ko mice

100 μ l of AAV-PhP.eB-CAG-hLG MN with a titer of $c=5*10^{12}$ vg/ml was applied *via* tail vein injection at an age of 6-7 months in male *Grn* ko mice. Non-injected age-matched male *Grn* ko mice were used as controls.

Motor function assessment

Rotarod test

A rotarod (# 3376O4R, TSE Systems) was used to assess motor function. The speed was accelerated stepwise from 4-40 rpm within 300 s as previously described⁴⁵. Mice were trained twice within one week before starting longitudinal rotarod measurements. The average latency to fall off the rotarod of three consecutive tests was calculated for each recording day.

Hind limb clasping test

Mice were recorded for 10 seconds while being lifted by their tail as previously described⁶³. Mice were scored based on the degree of cramping of their hind limbs recorded on two different days at 3 months p.i.. Mice showing no cramping obtained a score of 0, cramping for less than 25% of recording time a score of 1, more than 25% of recording time a score of 2, or more than 50% of the recording time a score of 3.

Mouse brain dissection and blood collection

Mice were sacrificed by CO₂ inhalation or by deep/lethal anesthesia and perfused with ice cold PBS. Brain tissue dissected from adult mice was either snap frozen in liquid nitrogen, mechanically pulverized and stored at -80°C for biochemical analysis, fixed in PFA for immunofluorescence staining or directly used for cell isolation.

Blood was collected 1 day before virus injection and at 1.5 months p.i. by facial vein puncture. Terminally, blood was collected before perfusion via cardiac puncture in EDTA-coated tubes and centrifuged (15,500 x g, 7 min, 4°C). For analysis the plasma fraction was used.

Mouse brain cell isolation

Mice were sacrificed by CO₂ inhalation or by deep/lethal anesthesia and perfused with ice cold PBS and directly subjected to microglia and astrocyte or neuron isolation. Neural cells were acutely isolated from adult mouse brain using MACS technology (Miltenyi Biotec). Brain tissue was dissociated into a single-cell suspension by

enzymatic digestion using the Adult Brain Dissociation Kit P (# 130-107-677, Miltenyi Biotec) and the gentleMACS™ Octo Dissociator (# 614 130-096-427, Miltenyi Biotec) according to manufacturer's instructions. Microglia and astrocyte isolation were performed from the same mouse brain. Briefly, the dissociated cell suspension was applied to a pre-wetted 100 µm cell strainer, cells were pelleted at 300 x g, 4°C, 10 min, pellets were washed twice and resuspended in 1 ml 0,5% (w/v) BSA/PBS. CD11b-positive microglia were magnetically labelled with 20 µl anti-CD11b MicroBeads (# 130-049-601, Miltenyi Biotec) and incubated for 20 min in the dark at 4°C with gentle shaking. Cells were washed by adding 1–2 ml of BSA/PBS. The cell pellets were resuspended in 1 ml BSA/PBS and applied together with 1 ml BSA/PBS onto the prepared LS columns (# 130-042-401, Miltenyi Biotec) placed into a QuadroMACS™ Separator (# 130-091-051, Miltenyi Biotec). The columns were washed with 3 × 3 ml BSA/PBS. The flow-through and the first wash containing the unlabeled cells was collected for astrocyte isolation. The columns were removed from the magnetic field, and microglia were flushed out using 5 ml BSA/PBS. To obtain a higher purity, the microglia containing eluate was applied onto pre-wetted MS columns (# 130-042-201, Miltenyi Biotec) placed into an OctoMACS™ Separator (# 130-042-108, Miltenyi Biotec), washed 3 x 0.5 ml and eluted with 1 ml BSA/PBS, then immediately stored on ice. For astrocyte isolation the microglia-depleted fraction including the first wash was pelleted and resuspended in 1 ml BSA/PBS, then 10 µl of FcR blocking reagent was added and incubated for 20 min, gentle shaking in the dark at 4°C, followed by adding 10 µl of anti-ACSA-2 MicroBeads (Anti-ACSA-2 MicroBead Kit, # 130-097-678, Miltenyi Biotec) and an additional incubation for 30 min. Cells were washed and astrocytes were magnetically separated as described for microglia. Neurons were isolated (Adult Neuron Isolation Kit mouse, # 130-126-603, Miltenyi Biotec) according to the manufacturer's instructions including a red blood cell removal and a debris removal step (Adult Brain Dissociation Kit P, # 130-107-677, Miltenyi Biotec). Isolated cells were washed twice with D-PBS (# 14040-133, Thermo Fisher Scientific) to remove BSA, pellets were snap frozen in liquid nitrogen and stored at -80°C until further biochemical analysis.

Mouse embryonic fibroblasts (MEF), HeLa and HEK293T cell culture

All MEF were generated as described before⁴. MEF, HeLa, and HEK293T were cultured in Dulbecco's modified Eagle's medium (DMEM) with GlutaMAX™-I (# 10566016, Thermo Fisher Scientific) supplemented with 10% (v/v) heat inactivated

FBS (# F7524, Sigma-Aldrich), 100 U/ml penicillin, and 100 µg/ml streptomycin (# 15140148, Thermo Fisher Scientific), and if required 1% non-essential amino acids (# 11140050, Thermo Fisher Scientific).

Primary culture of mouse microglia

Microglia were isolated from P11 pups using the MACS Technology (Miltenyi Biotec) as described above. Isolation was carried out under sterile conditions. 60,000 cells were plated in DMEM/F-12, HEPES (# 11594426, Thermo Fisher Scientific) supplemented with 10% (v/v) heat inactivated FBS (# F7524, Sigma-Aldrich), 100 U/ml penicillin, and 100 µg/ml streptomycin (# 15140148, Thermo Fisher Scientific).

Primary culture of mouse hippocampal neurons

Mouse hippocampal neurons were generated as described previously⁴⁵. In brief, E18 embryos were collected from CO₂-euthanized C57BL/6J wildtype mice. The hippocampi were isolated and dissected in ice-cold dissection buffer (HBSS, 1 mM sodium pyruvate, 10 mM HEPES pH 7.2, all from Thermo Fisher Scientific). Single cell suspension was obtained by pelleting the tissue (300 x g, 3 min, RT) and incubating it for 15 min at 37°C with 0.125% trypsin (# 25200-072, Thermo Fisher Scientific) and 25 U/ml benzonase (# E1014-25KU, Sigma-Aldrich) in DMEM with GlutaMAX™-I. After centrifugation (300 x g, 3 min, RT), tissue was washed in DMEM with GlutaMAX™-I and pelleted again (300 x g, 3 min, RT) before trituration in culture media (neurobasal media, # 21103-049, Thermo Fisher Scientific) with 100 U/ml penicillin, 100 µg/ml streptomycin, 0.5 mM L-glutamine (# 25030-024, Thermo Fisher Scientific) and 1x B-27 supplement (# 17504-044, Thermo Fisher Scientific) with 25 U/ml benzonase and subsequent centrifugation (300 x g, 3 min, RT). The single cells were plated onto poly-D-lysine- (10 µg/ml, # P7280-5MG, Sigma-Aldrich) and laminin- (10 µg/ml, # L2020-1MG, Sigma-Aldrich) coated plates in culture media. On DIV 7, 20% media was added and on DIV 14, cells were used for experiments.

Gene expression analysis

For quantitative real time PCR (qRT-PCR) approximately 10-20 mg of powdered mouse brain homogenates or between 400,000 and 2 million hiPSC -derived MGL or hNE were subjected to total RNA preparation using the QIAshredder and RNeasy Mini Kit (# 79656, Qiagen) according to manufacturer's instructions. 0.1-1 µg of RNA was reverse transcribed into cDNA using M-MLV reverse transcriptase (Promega) and oligo(dT) primers (Life Technologies). The following primer sets from Integrated DNA

Technologies were used: mouse *Lgmn* Mm.PT.58.5122210 (Exon boundary 10 to 11), mouse *Gapdh* Mm.PT.39a.1 (Exon boundary 2 to 3), human *LG MN* Hs.PT.58.21235685 (Exon boundary 3 to 4) and human *RPL22* Hs.PT.58.41088691(Exon boundary 3 to 4).

For quantification, cDNA levels were normalized to mouse *Gapdh* or human *RPL22* cDNA and relative transcription levels were analyzed using the comparative $\Delta\Delta C_t$ method (7500 Software V2.0.5, Applied Biosystems, Life Technologies). The *Lgmn* mRNA level of the microglia-enriched fraction was obtained from a NanoString dataset (Omnibus [GSE129709](https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE129709) <https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE129709>)¹⁰.

Cloning of m*Lgmn*

The mouse *Lgmn* cDNA was amplified from MEF cDNA prepared as described for “gene expression analysis”, following primers were used: *Lgmn* (XhoI) forward 5'-CCCGCTCGAGGCCACCATGACCTGGAGAGTGG-3' *Lgmn* (EcoRV) reverse 5'-AGCTTTGATATCTCAGTAGTGACTAAGAC-3'. The amplified *Lgmn* cDNA was sub-cloned into the XhoI/EcoRV sites of pcDNA3.1/Zeo(-). The *Lgmn* mutation leading to an inactive LG MN C191A variant^{40,68} was introduced by site-directed mutagenesis using the QuickChange Site-Directed Mutagenesis Kit (# 200519, Agilent Technologies) according to manufacturer's instruction. The Cys coding base triplet TGT was exchanged to GCT coding for Ala using following primers: *Lgmn*(mt)F 5'-GGTGTCTACATTGAAGCTGCTGAGTCTGGCTCCATGATGAACC-3'-*Lgmn*(mt)R 5'-GGTTCATCATGGAGCCAGACTCAGCAGCTTCAATGTAGAACACC-3'.

Design and production of adeno-associated virus.

AAV-hSyn-Cst7. A 603 bp long nucleotide encoding for cystatin-7 was cloned into the BamHI/EcoRI sites of pAAV-hSyn-EGFP (# 50465, Addgene) to receive the plasmid pAAV-hSyn-Cst7. To generate double-stranded adeno-associated virus of serotype 9 (AAV9), the plasmid and helper plasmid were transfected into HEK293T cells using polyethylenimine (# 24765, Polysciences). The virus was harvested after 72 h and purified from benzonase-treated cell lysates via an iodixanol density gradient (OptiPrep, Fresenius Kabi Norge). After rebuffering in lactose AAV titers were determined by real-time PCS on vector genomes using the SYBR Green Master Mix (Roche Molecular Systems).

AAV-PhP.eB-CAG-hLGMN. The AAV-PhP.eB-CAG-hLGMN vector used in this study was produced under research-grade conditions at SignaGen by triple transfection of adherent HEK293T cells. Briefly, HEK293T were transiently transfected after 48 h of culture using the corresponding Gene of Interest (GOI) plasmid, the corresponding capsid plasmid (AAV-PHP.eB), and the helper plasmid and PolyJet DNA transfection reagent (SignaGen) as transfection reagent. 72 h after transfection, cells were detached and harvested using sterile PBS. Harvested cells were lysed by three freeze/thaw cycles before an overnight benzonase treatment at 37 °C to digest residual DNA followed by high salt treatment for 1 h at 37°C. The crude lysate was further clarified by low-speed centrifugation. Full capsid AAVs were purified by ultracentrifugation in a cesium chloride (CsCl) gradient. A diafiltration step was then performed to concentrate the purified AAVs and reformulate them into PBS + 0.005% poloxamer 188 (# 13-901-CI, Corning) using Amicon Ultra-4 filter units (# UFC8100, Merck) with a 100 kDa MWCO membrane. Finally, a sterile filtration through a 0.22 µm membrane filter was performed. Vector genome titer was determined by qPCR using an ITR-specific primer-probe set. The final purified products were characterized with assays to measure identity, potency, and purity.

Lipofectamine 2000 mediated cDNA transfection

For transfection of HeLa and HEK293T cells Lipofectamine 2000 (# 11668030, Thermo Fisher Scientific) was used according to the manufacture's instruction. Briefly, 500 µl of 4 µg/ml plasmid solution in media was mixed with 500 µl DMEM with GlutaMAX™-I containing 20 µl Lipofectamine 2000 and incubated for 20 min at RT before dropwise addition onto HeLa cells at 50-70% confluency. After 6 h, the media was exchanged and after 36 h the media was replaced with 4 ml Opti-MEM® with GlutaMAX™-I media (# 51985-026, Thermo Fisher Scientific). Media and cells were collected 48 h after transfection.

siRNA Transfection

Lgmn siRNA (# M-044015-01-0005, siGENOME SMART pool, Dharmacon), control siRNA (#D-001210-04-20, siGenome non-targetting pool 4, Dharmacon) and mock reverse transfections were carried out with Lipofectamine™ RNAiMAX (# 13778030, Thermo Fisher Scientific). For each 10 cm dish 3 µl siRNA (20 µM), were diluted in 600 µl Opti-MEM™ (# 31985-062, Thermo Fisher Scientific) before adding 30 µl Lipofectamine™ RNAiMAX and then for complex formation incubated for 15 min at RT.

Trypsinized and washed MEF cells were added to reach a final volume of 6 ml culture media without antibiotics and a final siRNA concentration of 10 nM. The next day, media were exchanged to fresh culture media and 96 h after transfection cells were harvested and pellets were washed in PBS, snap frozen in liquid nitrogen and stored at -80°C.

Human iPSC culture

HiPSC experiments were performed in accordance with relevant guidelines and regulations. The female iPSC line A18944 was purchased from Thermo Fisher (# A18945), grown in Essential 8 Flex Medium (# A2858501, Thermo Fisher Scientific) on VTN-coated (# A14700, Thermo Fisher Scientific) cell culture plates with 5% CO₂ at 37°C, and split as small clumps twice a week after a 5 min incubation in PBS/EDTA. The *GRN* ko iPSC line was described before²².

Differentiation of human iPSC-derived to cortical hiMGL, hiNE, co-culture of hiNE with hiMGL and treatment with AAV-Cst7 or LGMN inhibitor.

HiPSC-derived hiMGL were differentiated as previously described²² following the protocol by Abud et al.⁶⁹ with modifications to improve yield and efficiency. HiMGL were used for monoculture experiments on day 16 of the differentiation. HiPSC-derived hiNE were differentiated as previously published⁷⁰ and used following day 60 of differentiation. HiNE were transduced with AAV-Cst7 at 500,000 gc/cell one week before co-culture with microglia. For co-culture experiments, hiMGL were added to differentiated neurons on day 12 of hiMGL differentiation and co-cultured for three weeks before collection for analysis. For LGMN inhibitor treatments, co-cultures were treated every 48 h from the start of co-culture with either 1 µM LGMN inhibitor (Roche) or a DMSO control for three weeks.

Conditioned media treatment of monocultured hiNE

Monocultured hiNE were maintained along with co-cultures, as described above. Half of the media was taken out of the monocultured hiNE and media from the co-cultures was added before collecting the monocultured hiNE 24 h later.

LGMN *in vitro* activity assay

A fluorescence-based activity assay was used to assess LGMN proteolytic activity of recombinant LGMN, or LGMN activity in lysates and media of the respective cells. Cell pellets or aliquots of powdered brain tissues were homogenized in LGMN-lysis buffer

(50 mM sodium citrate pH 5.0, 0.8% NP-40, 1 mM DTT), incubated 15 min (cell lysates) or 20 min (brain lysates) on ice, followed by a 15 min centrifugation at 15,000 x g, 4°C. Protein concentration was determined using the BCA protein assay (Pierce, Thermo Scientific) and indicated amounts of protein in 50 µl LGMN-lysis buffer were pre-incubated in black 96-well plates (FluoroNunc) at 37°C for 10 min, then 50 µl LGMN assay buffer (50 mM sodium citrate pH 5.0, 1 mM EDTA pH 8.0, 1 mM DTT and 200 µM substrate (Z-Ala-Ala-Asn-AMC (# I-1865.0050, BACHEM))) prewarmed at 37°C was added. Cleavage of the quenched fluorescence substrate was continuously measured for 30 min following the increase of the fluorescence signal (excitation, 390 nm; emission, 460 nm) using the Fluoroskan Ascent FL plate reader (Labsystems). The relative enzyme activity was calculated for a period of time with linear substrate turnover.

***In vitro* activation assays of recombinant pro-LGMN (rLGMN) or of the secreted pro-LGMN (sLGMN)**

Prior to LGMN activity assays mouse rLGMN (# 2058-CY-010, R&D Systems) or sLGMN proform needs to be autocatalytically activated at acidic pH. 50 ng rLGMN or 25 µl of the collected media of transfected HeLa cells or hiMGL/hiNE co-cultures was preincubated in 10 µl or 25 µl acidic activation buffer (100 mM sodium citrate pH 4.0 or 3.5, 1 mM EDTA, 50 mM NaCl) for 4 h or as indicated at 37°C. For the activity assay 40 µl LGMN-lysis buffer was added and LGMN activity was measured as described above. To investigate the inhibitory effect of PGRN on LGMN activity, 200 ng or the indicated amount of human recombinant PGRN (rPGRN, # 10826-H08H, Sino Biological Inc.) was either added to the activation assay or to the activity assay.

hLGMN ELISA

hLGMN was measured by an ELISA protocol previously established for PGRN by our group using the MSD Platform⁷¹. The ELISA consists of streptavidin-coated 96-well plates (streptavidin Gold Plates, # L15SA, MSD), a biotinylated polyclonal goat anti-human LGMN capture antibody (0.5 µg/ml, # BAF2199, R&D Systems), a polyclonal rabbit anti-human LGMN detection antibody (0.25 µg/ml, # NBP1-87793, Novusbio) and a SULFO-TAG-labelled goat polyclonal anti-rabbit IgG secondary antibody (0.5 µg/ml, # R32AB, MSD). All antibodies were diluted in 0.5% bovine serum albumin (BSA) and 0.05% Tween 20 in PBS (pH = 7.4) buffer. Recombinant human legumain/asparaginyl endopeptidase (# 2199-CY-010, R&D Systems) was used as a

standard (18.31 to 2343.75 pg/ml). In brief, streptavidin-coated 96-well plates were blocked overnight at 4°C in blocking buffer, then capture antibody (25 µl per well) was incubated for 1 h at RT, followed by four times washing (0.05% Tween 20 in PBS) and incubation for 2 h at RT with the samples diluted 1:2.5 in assay buffer (0.25% BSA and 0.05% Tween 20 in PBS (pH7.4)) or the recombinant human LGMN standard dilution. Plates were again washed four times with washing buffer before incubation for 1 hour at RT with the detector antibody. After four additional washing steps, plates were incubated with the secondary antibody for 1 h in the dark. Last, plates were washed four times with wash buffer followed by two washing steps in PBS. The electrochemical signal was developed by adding MSD Read buffer T (# R-92TC) and the light emission measured using the MSD MESO QuickPlex SQ120. The ELISA showed accurate results in spike recovery experiments (98%) and minimal measurement variation (CV = 4%) between replicates. For calculation of the sample concentration the MSD software Workbench v4 was used.

Plasma Neurofilament light-chain (NfL) analysis

Plasma Nfl levels were measured with the Quanterix Simoa® NF-light™ Reagent Kit (# 103186, Quanterix) following the manufacturer's instructions as previously described (Reifschneider, 2022). Plasma NfL levels were run on a Simoa HDX instrument (Quanterix) and interpolated against a calibration curve included in the Quanterix assay kit.

Generation of granulin peptides

Elastase generated granulin peptides were obtained by incubation of rPGRN with human neutrophil elastase (# RP-77526, Invitrogen). 50 ng/µl PGRN and 80 ng/µl elastase were incubated in 100 mM sodium citrate pH 6.0 overnight at 37°C, followed by buffer exchange to LGMN activation buffer. Aliquots were stored at -80°C.

Antibodies

Antibodies	Dilution		Source
	IB	IF	
Mouse anti-β-actin	1:5,000	--	# A 5316, Sigma-Aldrich
Rabbit anti-calnexin	1:5,000	--	# SPA-860, Stressgene
Rabbit anti-cystatin-7	1:2,500	1:250	# 50236, SinoBiological
Mouse anti-GAPDH	1:10,000	--	# AM4300, Invitrogen
Goat anti-human IBA1	--	1:250	# ab5076, Abcam

Rabbit anti-human IBA1	1:500	--	# PA5-27436, Thermo Fisher Scientific
Rat anti-mouse LAMP1	--	1:500	# sc-19992, Santa Cruz
Sheep anti-mouse LGMN	1:2,500	1:250	# AF2058, R&D Systems
Goat anti-human LGMN	1:1,000	1:250	# AF2199, R&D Systems
Chicken anti- MAP2	--	1:1,000	# NB300-213, Novus Biologicals
Rat anti-mouse PGRN, (clone 8H10)	1:50	--	generated ⁷²
Rabbit anti-human PGRN	1:1,000	--	# 40-3400, Thermo Fisher Scientific
Rabbit anti-human PGRN / granulin-peptides	1:1,000	--	# HPA008763, Atlas Antibodies
Rabbit anti-TDP-Ntlong	1:4,000	1:600	# 10782-2-AP, Proteintech
Rabbit anti-TDP-Ctlong	1:1,000	--	# 12892-1-AP, Proteintech
Rabbit anti-TDP-Ctshort	1:1,000	--	# TIP-TD-P09, Cosmo Bio
Rabbit anti-pTDP-43	1:5,000	--	# 80007-1-RR, Proteintech
Mouse anti-tubulin α	1:500	--	# T5168, Sigma-Aldrich
Mouse anti-tubulin β 3 (TUJ)	1:1,000	--	# 801201, BioLegend

The following secondary antibodies were used for immunoblots: horseradish peroxidase-conjugated donkey anti-goat IgG (H+L) (Dianova, 1:5,000), donkey anti-sheep IgG goat (Jackson Immuno Research, 1:10,000), goat anti-mouse IgG (Promega, 1:10,000), goat anti-rabbit IgG (Promega, 1:20,000), goat anti-rat IgG + IgM (L+M) (Dianova, 1:5,000), and generated mouse anti-rat IgG2c (1:1,000).

Immunohistochemistry

Cells seeded on coverslips in 24-well dish were fixed for 15 min in 4% paraformaldehyde and washed with PBS, then permeabilized for 10 min at room temperature in (0.1% Triton-X-100 in PBS for MEF and iPSCs, 0.1% Triton-X-100 and 0.1% saponin in PBS for *Cst7*-transduced hiN) and then washed with PBS again. SuperBlock (# 37515, Thermo Fisher Scientific) was used to block the coverslips for 1-2 h at RT. Primary antibodies were diluted in SuperBlock added overnight (iPSC) or for 2 h at 37°C (MEF). The coverslips were washed again in PBS and incubated in secondary antibodies (donkey anti-chicken Alexa 647 1:500, donkey anti-rat Alexa 647 1:500, donkey anti-sheep Alexa 555 1:500, donkey anti-rabbit Alexa 488 1:500, DAPI 1:5,000) diluted in SuperBlock for 90 min at RT in the dark. They were washed in PBS again and mounted with Fluoromount G (# 00-4958-02, Thermo Fisher Scientific).

Protein analysis and immunoblotting

Snap frozen cell pellets or powdered brain homogenate were lysed in NP-40 LGMN-lysis buffer (50 mM sodium citrate pH 5.0, 0.8% NP-40, 1 mM DTT), NP-40 STEN-lysis buffer (150 mM NaCl, 50 mM Tris–HCl pH 7.6, 2.5 mM ETDA, 1 % NP40) or RIPA-lysis buffer (150 mM NaCl, 20 mM Tris–HCl pH 7.6, 2.5 mM ETDA, 1% NP-40, 0.1% sodium dodecyl sulfate (SDS), 0.5% sodium-desoxycholate) as indicated. NP-40 STEN- and RIPA-lysis buffer were supplemented with protease inhibitor cocktail (# P8340, Sigma-Aldrich) and phosphatase inhibitor (# 4906845001 PhosStop™, Sigma-Aldrich). Lysates were centrifuged for 20 min, 17,000 x g, 4°C. The protein concentration of the soluble fraction was determined using the BCA protein assay (Pierce, Thermo Fisher Scientific) and equal amount of protein were separated by SDS-PAGE and transferred to polyvinylidene difluoride membranes (Immobilon-P, Merck Millipore). Membranes were blocked for one hour in I-Block™ (# T2015, Thermo Fisher Scientific). Proteins of interest were detected by the indicated primary antibodies followed by horseradish peroxidase-conjugated secondary antibodies detected by ECL Plus (# 32132X3, Pierce™ ECL Plus Western Blotting Substrate, Thermo Fisher Scientific). For the quantitatively analysis, images were taken by a Luminescent Image Analyzer LAS-4000 (Fujifilm Life Science, Tokyo, Japan) and evaluated with the Multi GaugeV3.0 software (Fujifilm Life Science, Tokyo, Japan).

Statistical analysis

Data are presented as mean ± s.d. or mean ± s.e.m. Statistical significance was calculated for comparison of two sample groups by unpaired, two-tailed Student's t-test, and for multiple comparison by one-way ANOVA with Tukey's or Dunnett's post hoc test and indicated as ns, not significant; $P > 0.05$; * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$; **** $P < 0.0001$. All data were analyzed using GraphPad Prism 7 (GraphPad Software Inc.).

Data availability

All data and information are included in the manuscript. Supplementary information and source data are provided with this article. Data are available from corresponding authors upon reasonable request.

Acknowledgement

We thank Ignacio Paris for image analysis, Lis de Weerd for help with tissue collection and the BELNEU consortium for clinical and pathological characterization for inclusion in the cohort of FTD patients, and the Institute Born-Bunge for the brain material. We thank Benedikt Wefers and Wolfgang Wurst for generating *Lgmn* ko mice. We further thank Joseph W. Lewcock for helpful discussions, Sarah De Vos and Kirk Henne for their inputs on study design, Ray Low for generation of PTV:PGRN material and Tim Earr for *in vivo* study assistance. Figures 4a and 5d&j were created with BioRender.com. This work was supported by a grant of the Alzheimer's Association (to AC, CH, DP, MD) and the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy within the framework of the Munich Cluster for Systems Neurology (EXC 2145 SyNergy – ID 390857198). Parts of the project were also supported by the Koselleck Project (HA1737/16-1) of the DFG and the NOMIS foundation. CVB was supported by the Flemish Government initiated Methusalem excellence program, the Flanders Impulse Program on Networks for Dementia Research (VIND), the Research Foundation Flanders (FWO) and the Belgium Alzheimer Research Foundation (SAO). EW received a postdoctoral fellowship of the FWO.

Todd Logan, BioMarin Pharmaceutical Inc., San Rafael, CA, USA.

Anika Reifschneider, Bristol Myers Squibb, Munich, Germany.

Author contributions

AC and CH conceived and designed the study and wrote the manuscript with the help of MTM, MR and SR. SR, MR and DP designed, performed and analyzed iPSC experiments. MR, DE, HR and AR performed and analyzed primary neuronal and microglial experiments. KB cloned LGMN constructs. MR performed and analyzed HeLa conditioned media-treated neuron experiments. KB and GW performed

experiments with MEF, mouse brain and FTLD-*GRN* patient material and recombinant LGMN. MTM and MR performed *in vivo* mouse experiments and MTM analyzed the AAV-overexpression study in *Grn* ko mice. MJS, TL and GDP generated, MR analyzed the PTV:PGRN study. QM conducted the cystatin experiments. AA and SE generated and purified the AAV9-Cst7. CVB and EW provided validated FTLD-*GRN* patients brain samples. MD co-initiated the study and performed liver lysosome isolation on mice provided by AC, MTM and TR. SG and BB discovered and characterized the legumain inhibitor (LGMN inh). All authors commented on the manuscript.

Extended data methods

Experimental mouse models

The second *Grn* ko mouse model and the *Grn* ko/h*TfR*mu/hu ki were previously generated and characterized. *Grn* ko on a C57Bl6/J background were obtained from Jackson Laboratories (JAX strain 013175)¹. *TfR*mu/hu ki mice (also on a C57Bl6/J background) expressing a chimeric TfR receptor (human TfR apical domain knocked into the mouse receptor) were developed by generating a knock-in of the human apical TfR mouse line using CRISPR, as described previously². Homozygous *TfR*mu/hu male mice were bred to female *Grn*^{+/-} mice to generate *Grn*^{-/-} x *TfR*mu/hu mice. Constitutive *Lgmn* ko mice was generated on a C57Bl6/J background by CRISPR/Cas9 induced deletion of exon 3 of the *Lgmn* gene (842bp) leading to a frameshift knockout by an early stop codon.

Mouse handling and tissue collection at Denali Therapeutics

Animal weights were collected at the start and end of the study. Mice received therapeutic treatment *via* intravenous (IV) tail vein injection (~200 µl total injection volume). At indicated endpoints animals were anesthetized with tribromoethanol. Following plasma collection, mice were transcardially perfused with ice-cold PBS.

Tissues were then collected, weighed, frozen on dry ice and stored at -80°C for subsequent analysis.

Isolation of liver lysosome

As described before³ mice were injected with 4 µl/g bodyweight with 17% (w/v) tyloxapol in 0.9% NaCl four days prior to killing and organ removal. After the removal of the liver, the liver was homogenized in 5 ml ice-cold 0.25 M sucrose with four strokes at 1,000 rpm in a Potter-Elvehjem homogenizer. The homogenate was subsequently centrifuged for 10 min at 1,000 x g in a tabletop centrifuge, the supernatant was removed and the pellet re-extracted with another 2 ml of 0.25 M sucrose and centrifuged again. The pooled supernatants (postnuclear supernatant; PNS) were used for differential ultracentrifugation: 9 ml of the PNS were centrifuged at 56,000 x g for 7 min (70.1 Ti rotor, Beckmann, Coulter). The supernatant was removed, the pellet (mitochondria / lysosome fraction; ML) homogenized in 8 ml 0.25 M sucrose and centrifuged again at 56,000 x g for 7 min. The final pellet was resuspended in 3 ml of sucrose solution with a density of 1.21 g/ml. This fraction was overlaid with sucrose solutions with a density of 1.15 g/ml (3 ml), 1.14 g/ml (3 ml) and finally 1.06 g/ml to obtain a discontinuous sucrose gradient. The sucrose gradient was centrifuged at 110,000 x g for 150 min in a swinging bucket rotor (SW41 Ti rotor, Beckmann Coulter). Lysosomes were collected from the interphase between the sucrose solution with a density of 1.14 g/ml and 1.06 g/ml.

Treatment of mice with PTV:PGRN

PTV:PGRN was generated at DENALI Therapeutics as previously described (Logan et al.). Mice received 10 mg/kg PTV:PGRN *via* intravenous (IV) tail vein injection (~200 µl total injection volume) and tissue collected either 7 or 14 days after treatment.

Transfection of MEF with *Grn* cDNA

MEF *Grn* ko were stably transfected with mouse *Grn* cDNA as described before⁴.

Cloning of *Cst3* and *Cst7* constructs.

Mouse cystation-3 (# MR225378, OriGene) and cystatin-7 (# MR222507, OriGene) myc-tagged cDNA clones were subcloned into the BamHI/EcoRI sites of pcDNA3 using the following primers:

Cst3 (BamHI) forward 5'-CCCGGATCCCCAACCATGGCCAGCCCGCTGC-3'

Cst7 (BamHI) forward 5'- CCCGGATCCCCAGCCATGCCCTGGTCCTGG -3'

Cst3/7 (EcoRI) reverse 5'- CGGAATTCTTAAACCTTATCGTCGTCATCC -3'

Six hundred three base pairs (603 bp) encoding for cystatin-7 were cloned into the BamHI/EcoRI sites of pAAV-hSyn-EGFP (# 50465, Addgene). Serotype AAV9 (pAAV-GOI) virus particles were produced in HEK 293T cells by co-transfection with pAAV-RC, pHelper and pAAV-GOI using Lipofectamine 2000 (ThermoFisher Scientific). After 72 h cells were detached with 0.5 M EDTA and centrifuged for 5 min at 3000 rpm. The pellet was resuspended in 250 μ l Neurobasal Medium (ThermoFisher Scientific) followed by 4 freeze-thaw cycles in a dry ice ethanol bath and a 37°C water bath for 2 min per bath and cycle. Centrifugation for 10 min at 10,000 x g generated the viral particles containing supernatant. AAV was stored at -80°C until further use.

***In vitro* determination of pIC₅₀ for the LGMN inhibitor**

A modified fluorescence-based activity assay was used to assess the potency of the LGMN inhibitor to inhibit LGMN activity *in vitro*. Recombinant LGMN stored in 25 mM HEPES/NaOH pH 7, 300 mM NaCl, 200 mM trehalose was activated at a concentration of 0.1 mg/mL for 2 h at room temperature in 50 mM sodium acetate pH 4.0. Assay buffer was 20 mM Na-phosphate/citrate pH 5.8, 1 mM EDTA, 0.1% CHAPS. The pre-activated LGMN (c=0,1 nM) was incubated with 10 μ M of peptide Z-AAN-Rh110 and different doses of LGMN inhibitor. Excitation and emission wavelengths were 485 nm and 520 nm, respectively. Fluorescence was measured after 15 min and 30 min incubation.

Determination of pIC₅₀ for the LGMN inhibitor in HEK293A cells

HEK293A overexpressing LGMN were cultured using DMEM (Gibco 31966) supplemented with 10% FCS, 1% Penicillin/Streptomycin and 0.8 mg/ml Geneticin. On day before the assay 16.000 cells/well were plated in 384 well plates. At the assay day cells were treated with dose responses of LGMN inhibitor or DMSO control. Final DMSO concentration for all conditions was 0.6%, and compounds were tested in a 16-point-dose response starting at 60 μ M. Cells were incubated with LGMN inhibitor for 2 h, prior to addition of fluorogenic substrate **S** (Roche, final concentration 60 μ M)⁵. After addition of substrate cells were incubated for 5 h and the effect was detected by measuring fluorescence intensity at 460 nm after excitation at 380 nm in the living cells.

Protease selectivity screen

To test the selectivity of the LGMN inhibitor, pIC₅₀ values for different proteases were determined using the Protease Assay Service from REACTION BIOLOGY (<https://www.reactionbiology.com/services/target-specific-assays/protease-assays>). pIC₅₀ for LGMN was determined by Roche, Basel.

Immunofluorescence of mouse brain tissue

Freshly isolated brain hemispheres were post-fixed in 4% paraformaldehyde in PBS (Thermo Scientific, J19943-K2) for 24 h at 4°C. Brain hemispheres were transferred to PBS with 0.02% NaN₃ and stored at 4°C until further use. Brain hemispheres were cut in 40 µm sections using a vibratome (Leica VT1200S). Immunofluorescence was performed on free floating sections. Sections were blocked with blocking solution (4% bovine serum albumin (BSA, Sigma A8022-100G) and 0.1% fish skin gelatin (Sigma G7041) in PBS with 0.4% Triton-X) for 1 h at RT. Primary antibodies, hLGMN (R&D, AF 2199, c= 0.4 µg/ml), MAP2 (Novus Biologicals, 1:1000, NB300-213), IBA1 (GeneTex, 10042, c=0.06 ng/µl), GFAP (DAKO, Z0334, c=2.9 µg/ml) were diluted at the indicated concentration in blocking buffer and brain sections were incubated overnight at 4°C in the primary antibody solutions. The next day the sections were washed three times with PBS with 0.1% Tween® 20 and subsequently incubated with fluorophore-coupled secondary antibodies (Thermo Fisher Scientific, donkey, c=4 µg/ml) diluted in secondary antibody buffer (4% bovine serum albumin (BSA, Sigma A8022-100G) and 0,1% fish skin gelatin (Sigma G7041) in PBS) with DAPI (c=1 µg/ml) for 2 h at RT. After three washing steps in PBS with 0.1% Tween 20 sections were mounted with Fluoromount-GTM (Invitrogen, 00-498-02).

Image acquisition

Full brain hemispheres were imaged at 4x with a Leica DMi-8 epifluorescence microscope with a DFC9000GT camera. Image mosaics were merged using the Leica LAS X software suite. Representative images were acquired on a Zeiss LSM800 Axio Observer 7 confocal microscope with a 40x oil immersion objective (NA 1.3). A z-stack was acquired and confocal images show an orthogonal projection of six images with a z-stack size of 0.4 µm. Post-processing (adjustment of brightness) of full brain scans was performed in ImageJ and brightness of confocal images was adjusted with the Zen 3.2 (blue edition) software in the same way for all conditions.

Extended Data Fig. 1: Elevated LGMN maturation and activity upon PGRN deficiency results in altered cathepsin processing.

a, Processing of cathepsin D (CatD) and L (CatL) by LGMN is shown schematically. **b**, Representative immunoblots of MEF isolated from wt and *Grn* ko mice probed for CatD and CatL. MEF were either non- (-), control (*ctrl*) or *Lgmn* siRNA-transfected. CatD, and CatL, proform (p), single chain (sc), heavy chain (hc) are indicated. **c**, CatD and CatL maturation are quantified and normalized to wt (n=4). **d**, Representative immunoblots of liver lysosomes isolated from 6 months old *Lgmn* ko and wt mice probed for CatD and CatL. Data are mean \pm s.d; unpaired two-tailed t-test, *p<0.05, **p<0.01, ****p<0.0001.

Extended Data Fig. 2: Enhanced LGMN activity of *Grn ko* mice and MEF is rescued upon PGRN expression.

a, Representative immunoblots of MEF wt, *Grn ko* and *Grn ko* stably transfected with a mouse *Grn* cDNA probed for PGRN, LGMN, and β-actin to verify equal loading. **b**, LGMN substrate turnover and quantification of LGMN activity normalized to MEF wt of biologically independent duplicates is shown as mean ± s.d.. **c**, Schematic of PTV:PGRN single dosing study in *Grn ko/hTfR ki*. **d**, LGMN activity of a *Grn wt*, *Grn ko*, and *Grn ko* treated with a single 10 mg/kg i.v. dose of PTV:PGRN for 7 d and 14 d. Data indicate the mean normalized to wt. (n=6 mice per genotype and treatment, 3-4-month-old). **e**, Representative immunoblot for LGMN in total brain homogenate of wt and *Grn ko* non-treated and treated mice. Proform (LGMN_p), mature form (LGMN_m), unspecific band (asterisk) are indicated, β-actin verified equal loading. Quantification of LGMN immunoblot signals normalized to wt (n=6 mice per genotype and treatment).

Statistical significance was determined using one-way ANOVA and Tukey's post hoc test: ns, not significant; * $P < 0.05$, ** $P < 0.01$, **** $P < 0.0001$. *P* values and statistical source data are provided.

Extended Data Fig. 3: PGRN and LGMN are enriched in microglia.

Representative immunoblots for PGRN and LGMN in microglia-, astrocyte- and neuron-enriched brain cell fractions isolated from 10-month-old mice. Enrichment of each cell fraction is verified by immunoblotting for IBA1, GFAP and TUJ. Equal amounts of protein were loaded for all cell types, calnexin expression varies between cell types. n=2 mice per cell type and genotype.

Extended Data Fig. 4: LGMN deficiency results in reduced generation of single granulins in liver lysosomes.

a, Representative immunoblot of liver lysosome preparation of wt and *Grn* ko mice probed for LGMN, PGRN, granulins, with β -actin and LAMP1 as loading control for post nuclear supernatant (PNS) and lysosomes (Lys). **b**, Immunoblot of liver lysosome preparation of *Lgmn* wt and ko mice, probed for LGMN, PGRN and granulins. Data are mean \pm s.d. of granulins in lysosome preparation from individual mice (n=5-6); unpaired two-tailed t-test; *p<0.05, *P* values and statistical source data are provided.

Extended Data Fig. 5: LGMN inhibition by cystatin C and cystatin F.

a, Dose-dependent inhibition of recombinant LGMN via recombinant cystatin C (CSTC) (left) and cystatin F (CSTF) (right). Nonlinear regression (curve fit; variable slope (4 parameters)), top, bottom and IC_{50} are indicated. Data points show the mean \pm s.d. normalized to LGMN activity at 0 nM inhibitor (N=3 technical replicates). **b-c**, HEK 293T cells were transfected with *Cst3*, *Cst7* or pcDNA3 (Control). **b**, Immunoblotting indicates proform (LGMN_p), intermediate (LGMN_i) and mature form (LGMN_m) of LGMN, and CSTC and CSTF expression. β -Actin was probed to verify equal loading. **c**, In vitro LGMN activity assay of cell lysates. Data are mean \pm s.d. of biologically independent experiments normalized to control (n=3). Statistical significance was determined by one-way ANOVA and Dunnett's multiple comparisons post-hoc test: * $p < 0.05$, **** $p < 0.0001$.

Extended Data Fig. 6: Potency and selectivity of LGMN inhibitor.

a, Dose-dependent inhibition of pre-activated recombinant LGMN by the LGMN inhibitor. An IC_{50} of 7.3 nM with a 95% confidence interval from 6.9-7.7 nM was determined (Nonlinear regression curve fit; variable slope (4 parameters)). Data points show the mean of six technical replicates \pm s.d. **b**, Dose-dependent inhibition of LGMN in HEK293A cells by the LGMN inhibitor was determined using a cell permeable fluorogenic LGMN substrate. Effects of test compounds were normalized to effect of reference compound and DMSO control. An IC_{50} of 153.8 nM with a 95% confidence interval from 138.8-170.1 nM was determined (Nonlinear regression curve fit; variable slope (4 parameters)). Data points show the mean of four biological replicates \pm s.d. **c**, *In vitro* selectivity screen for the LGMN inhibitor. Proteases with a pIC_{50} below the limit of detection of 4 are depicted in light green, proteases having a $\text{pIC}_{50} > 4$ in dark green.

4. DISCUSSION

4.1. AAV(L):bPGRN - AN ADVANCED PGRN REPLACEMENT THERAPY APPROACH

To date, there is no disease-modifying treatment available for FTD. As a monogenic disease, the subtype FTLD-*GRN* is ideally suited for the development of therapeutics and to study their effect on the hallmark FTD phenotypes. In this thesis a novel therapeutic approach was introduced and assessed for its potential as a potential treatment for FTLD-*GRN* (3.1.). A liver-targeting adenovirus-associated virus, AAV8^{243,244}, encapsulates a construct that expresses human PGRN fused to the single-chain variable fragment of an IgG engineered to bind to the murine TfR (AAV(L):bPGRN expressing 8D3:PGRN). Upon a single-dose *intravenous* administration in mice, robust expression was achieved in the liver and human PGRN could be detected in the plasma and brains of the treated animals. Treatment was well tolerated and the toxicological assessment of different tissues and blood parameters raised no safety concerns. In both *Grn* KO and *Grn* and *Tmem106b* DKO mice, FTLD-*GRN*-related phenotypes could be ameliorated or reversed by AAV(L):bPGRN treatment, showing that this approach is indeed promising for the treatment of FTLD-*GRN*.

4.1.1. AAV(L):bPGRN AND PTV:PGRN – NOVEL TREATMENT APPROACHES FOR FTLD-*GRN*

AAV(L):bPGRN is a potential alternative to the recently described PTV:PGRN – a recombinant human PGRN that contains a similarly engineered TfR-binding domain for facilitated transcytosis across the BBB¹³³. This strategy was also successfully validated in *Grn* KO mice. Importantly, PGRN levels in the brain upon PTV:PGRN treatment were up to five-fold higher compared to the administration of PGRN without an engineered TfR-binding domain. Consequently, dysregulated lipids in the *Grn* KO brain, such as BMP and glucosylsphingosine, were fully normalized after PTV:PGRN treatment¹³³. Whether the administration of AAV(L):bPGRN results in brain PGRN levels similar to those achieved *via* PTV:PGRN can't be concluded from these two studies alone, as the ELISA used in the PTV:PGRN study differed significantly from the one used in the AAV(L):bPGRN study. A side-by-side comparison of both therapeutic approaches would therefore be necessary to directly compare brain PGRN levels. Nevertheless, as in the PTV:PGRN study, the brain lipidome could be fully normalized with AAV(L):bPGRN¹³³. Microglial activation, assessed by Cd68 and Trem2 levels, as well as lipofuscin accumulation and CSF NfL concentration were all completely rescued as well¹³³.

The main advantage of AAV(L):bPGRN is the single-dose treatment scheme, avoiding many injections over years, which would most likely be necessary in the case of a PTV:PGRN treatment paradigm. However, the repeated dosing of PTV:PGRN has the advantage of a better control over PGRN levels, allowing corrections, if and when needed. This is critical, as increased PGRN levels have also been associated with various forms of cancer^{105,106}. Chronically elevated PGRN levels may therefore increase the risk of developing tumors. Furthermore, the use of the AAV8 serotype leads to the broad transduction of hepatocytes, which has been shown to trigger immune responses in the liver²⁴⁵. For these reasons, the chemical and microscopic pathological investigations of multiple tissues were performed after eight months of treatment in the AAV(L):bPGRN study and no abnormalities could be detected. Treatment in patients would of course greatly exceed this time frame and the potential development of tumors will therefore have to be monitored carefully in early clinical trials. Another potential issue with both approaches is the risk of anti-drug antibodies developing as a defense mechanism of the immune system directed against the therapeutic, which would result in its degradation²⁴⁶. This is a longstanding issue in the pharmaceutical industry and solutions exist, such as the administration of immunosuppressive drugs after screening for potentially reactive patients²⁴⁶.

Taken together, the study by Logan *et. al* and the one presented here (3.1.) complement each other by presenting a variety of readouts relevant for FTLD-GRN that could be ameliorated by peripheral treatment with the brain-penetrant biotherapeutics PTV:PGRN and AAV(L):bPGRN. Both the sub-chronic treatment in the DKO mouse study and the chronic phase treatment in *Grn* KO mice were successful, establishing this as a viable therapeutic paradigm for both pre-symptomatic and symptomatic FTLD-GRN patients. This is particularly important for this disease, as pre-symptomatic patients can easily be identified based on their plasma PGRN levels⁹⁴⁻⁹⁶. Both treatment schemes also appeared to be safe in the assessed time frame and achieved a widespread biodistribution, raising PGRN levels extracellularly and intracellularly¹³³. PTV:PGRN is currently in clinical development in a phase I/II study, its safety and efficacy in humans will therefore soon be known (clinical trial ID: NCT05262023).

4.1.2. BRAIN-PENETRANT PGRN REPLACEMENT IN COMPARISON WITH ALTERNATIVE FTLD-GRN TREATMENT APPROACHES

Besides PTV:PGRN, several other FTLD-GRN drugs are currently in clinical development, all aiming at raising PGRN levels to counteract the haploinsufficiency of PGRN that is causative of disease in FTLD-GRN patients³.

One approach is PGRN replacement by AAV-based gene therapy^{234,235}. Unlike AAV(L):bPGRN, in this case the virus is injected directly into the CNS *via cisterna magna*

injection. This approach rescued *Grn* KO phenotypes in early mouse studies, but a recent publication failed to show a rescue of brain phenotypes upon AAV-based PGRN expression in the CNS^{234,235,239}. Biodistribution issues will most likely be even more pronounced in patients, considering the much larger size of the human brain. This was already shown by comparing AAV delivery in non-human primates and mice: AAV-driven transgene expression was mainly observed in the cortex and spinal cord in non-human primates^{236,237}. PGRN expressed in these tissues, rather than in peripheral ones, might not be distributed as homogeneously as it would have to diffuse through the extracellular space, while PTV:PGRN and 8D3:PGRN reach the brain through the circulatory system and can therefore be uniformly delivered²³⁸. In the PTV:PGRN study by Logan *et al.*, uptake by both neurons and microglia was shown¹³³. In the original AAV(L):bPGRN manuscript, as presented in this thesis (3.1.), biodistribution was not assessed beyond whole-brain PGRN concentrations. In the revision phase, however, its regional distribution was also investigated by immunofluorescence and the brain-wide distribution of 8D3:PGRN was confirmed, as well as its uptake by neurons, microglia, and astrocytes (data not shown). The PGRN signal was further strongly detected throughout the whole brain vasculature and in the choroid plexus, indicating the constant transcytosis of 8D3:PGRN into the brain. Lastly, a potential *caveat* related to a brain-directed AAV delivery strategy is the risk of puncturing the medulla, in addition to the neuroinflammation which was also previously shown to be caused by this administration route^{236,240}.

Another strategy, currently in phase III clinical trials, is to block the cellular uptake of PGRN using an anti-sortilin antibody. This approach successfully raised PGRN levels in the CSF and plasma of FTLD-*GRN* patients^{232,233}. However, an issue with this paradigm is that PGRN is only targeted indirectly *via* the blocking of sortilin. This raises safety concerns, as sortilin performs a variety of functions in the brain. Its ligands include different neurotrophins and pro-neurotrophins, neurotensin, and ciliary neurotrophic factor, all critical to the maintenance of brain homeostasis²⁴⁷. In another study for example, the genetic ablation of sortilin resulted in a compromised BBB²⁴⁸. Besides the potential side effects arising from the impairment of the other functions of sortilin, this approach only raises PGRN levels extracellularly. As lysosomal dysfunction is a primary phenotype in PGRN deficiency, it is unlikely that this therapeutic approach will have a sustained effect on FTLD-*GRN* pathology^{3,249}.

Both of these therapeutics are in clinical trials, they might therefore still be suitable disease-modifying treatments for FTLD-*GRN* if the studies show positive results in their clinical outcomes.

4.2. GRN AND TMEM106B DKO MICE AND hiPSC-SYSTEMS AS *BONA FIDE* TRANSLATIONAL MODELS OF FTLD-GRN

To test the effect of AAV(L):bPGRN (3.1.), mice harboring a DKO of *Grn* and *Tmem106b* were used as a model of FTLD-GRN¹⁶⁹. In addition, a newly developed hiPSC model with the same DKO was generated to study the effect of PGRN replacement in disease-relevant cell types and in a fully human system.

The DKO mouse model was originally described independently by three laboratories as a *bona fide* FTLD-GRN model exhibiting a number of disease-relevant phenotypes^{162,169,170}. All the studies showed the impairment of lysosomal degradation and autophagy, as well as microglial and astrocytic hyperactivation. Additionally, demyelination and neurodegeneration were observed in both the spinal cord and the brain of DKO mice^{162,169,250}. As a consequence, the transgenics used in Werner *et al.* and Feng *et al.* also presented with early-onset motor impairments and a premature death at around 4.5 months of age^{162,169}. Most importantly, these mice showed TDP-43 pathology in the form of cytosolic aggregates positive for pTDP-43 and RIPA-insoluble pTDP-43^{162,169,250}.

It is important to keep in mind, that FTLD-GRN patients usually have a *GRN* mutation in only one allele that causes haploinsufficiency of the protein⁷⁴. Homozygous *GRN* mutations, similar to the *Grn* KO, are ultra-rare and cause NCL^{97,125}. However, animals heterozygous for *Grn*, did not show any obvious phenotypes^{125,251,252}. The *Grn* KO mouse model, albeit rather being a model for NCL than FTLD-GRN, has robust phenotypes that replicate pathologies of both diseases¹²⁵. These include lysosomal dysfunction, neuroinflammation, as well as weak TDP-43 pathology in aged mice^{125,130,228}. Nevertheless, without pronounced neurodegeneration and TDP-43 pathology, as well as behavior phenotypes, *Grn* KO mice lack important FTLD-GRN hallmarks. Even though the KO of both *Grn* and *Tmem106b* does not recapitulate the genetic background of FTLD-GRN, the presence of multiple and robust disease-relevant phenotypes establishes DKO mice as an ideal model to study the efficacy of novel treatment approaches, such as AAV(L):bPGRN.

4.2.1. AAV(L):bPGRN PARTIALLY RESCUES DKO PHENOTYPES IN MICE

Because of their aggressive course of pathology and the premature death at 4.5 months of age, the choice was made to treat the DKO mice in a preventive fashion when evaluating the efficacy of AAV(L):bPGRN. Mice were therefore injected already at six weeks of age. Rescue of the phenotypes originally described in Werner *et al.* was assessed, namely motor impairment, dysfunctional protein degradation, accumulation of p62, TDP-43, and lipofuscin, and lastly neurodegeneration¹⁶⁹. These readouts were complemented by the comprehensive omic analyses of global brain lipids and gene transcripts.

4.2.1.1. IMPROVEMENT OF MOTOR IMPAIRMENT AFTER AAV(L):bPGRN TREATMENT

Although motor impairment, caused by the loss of upper and lower motor neurons, is much more common in ALS patients, it has also been documented as happening sporadically in FTLD-*GRN* patients^{23,253,254}. Following the observation that DKO mice present with severe motor deficits, rotarod performance was measured longitudinally in order to investigate their decline^{162,169,170}. DKO mice rapidly worsened in their performance, while AAV(L):bPGRN-treated DKO mice showed a slower rate of decline and stabilized 4 weeks after treatment, at an age of 10 weeks. The improvement in motor performance was confirmed by testing hindlimb claspings and whether it was possible to flip the mice over. Our findings are in line with another study performed in DKO mice which tested direct CNS delivery of an AAV expressing PGRN²³⁹. AAV treatment almost completely rescued motor performance in the open field, another flipping test, and stride length. These phenotypes were rescued despite only modest brain PGRN expression levels post injection. Therefore the motor impairment was likely primarily caused by the loss of lower motor neurons, since the neurodegeneration, along with the other pathological phenotypes, could only be ameliorated in the spinal cord, where a robust PGRN expression was observed²³⁹.

4.2.1.2. AAV(L):bPGRN TREATMENT RESTORES LYSOSOMAL FUNCTION

PGRN plays important roles within the lysosome and the KO of *Grn* alone was shown to dysregulate lysosomal homeostasis in mice (see 2.2.). This includes an enhanced lysosomal protease activity, lipidome alterations, lipofuscin accumulation, and the impairment of other protein degradation pathways, such as autophagy and the ubiquitin-proteasome system (reviewed in Simon *et al.*³). Other studies already showed, in part, that these pathologies can be rescued by PGRN replacement in *Grn* KO mice, either by AAV-mediated expression in the brain or by PTV:PGRN treatment^{133,234}. Arrant *et al.* investigated lipofuscin accumulation and lysosomal enzyme activity, and their AAV treatment normalized both phenotypes²³⁴. Rescue of lipofuscin accumulation, lipidome alterations, and lysosomal membrane damage was also achieved by Logan *et al.* after PTV:PGRN treatment¹³³.

In the DKO mouse model the lysosomal dysfunction is strongly exacerbated^{162,169,170}. It is therefore not trivial that PGRN replacement in DKO mice would be sufficient to also achieve a similar rescue. In the spinal cord of DKO mice, a CNS-delivered PGRN-expressing AAV successfully reduced lipofuscin and CTSD levels, but not in the brain²³⁹. In this study, the elevated protein levels of ubiquitin, saposin D, LC3, and p62 were analyzed as markers for impaired protein degradation pathways increased in DKO mice¹⁶⁹. All of these proteins were at least partially renormalized after AAV(L):bPGRN treatment. In addition, brain

lipidomics and transcriptomics were also performed as part of this study. Lipidome alterations, previously uncharacterized in DKO mice, largely overlapped with those observed in *Grn* KO mice¹³³. Consequently, lysosomal lipids such as various BMP species and glucosylsphingosine were rescued to the same extent¹³³. Similarly, the gene expression levels of lysosomal proteases and general lysosomal markers, such as *Lamp1* and *Lamp2*, were strongly increased in DKO mice, as shown before¹⁶⁹. AAV(L):bPGRN treatment fully reversed these expression changes as well. In conclusion, lysosomal dysfunction in DKO mice was rescued by AAV(L):bPGRN treatment. However, lipofuscin accumulation, an important phenotype that is also observed in patients, could not be analyzed conclusively, due to the high inter-animal variability observed^{128,168}.

4.2.1.3. NEUROINFLAMMATION IS SIGNIFICANTLY REDUCED AFTER AAV(L): bPGRN TREATMENT

The FTLD-*GRN* hallmark neuroinflammation is recapitulated already by *Grn* KO mice, as observed by microglial activation and astrogliosis, but strongly further enhanced in DKO mice^{162,169,170,226,228,231}. In previous studies, microglial activation, as assessed by Cd68 immunofluorescence, could be successfully normalized by direct CNS delivery of an AAV expressing PGRN or by PTV:PGRN treatment^{133,234}. In addition, PTV:PGRN treatment normalized astrocyte numbers and the brain concentrations of Trem2¹³³.

Here, bulk RNA sequencing of DKO mouse brains revealed a broad correction of microglial and astrocytic activation markers upon treatment with AAV(L):bPGRN. Validation by immunofluorescence confirmed a reduction in astrocyte numbers and Cd68 signal. However, the number of microglia was not affected as the signal of the microglial marker Iba1 was not reduced after treatment. Although the normalization of microglial activation markers in the whole-brain transcriptome analysis argues for a shift of microglial identity to a more homeostatic state, a detailed analysis using single-cell RNA sequencing of sorted microglia would be necessary to validate this statement.

4.2.1.4. RESCUE OF NEURODEGENERATION, BUT NOT DEMYELINATION, AFTER AAV(L): bPGRN TREATMENT

DKO mice present with severe neurodegeneration, as previously shown by the loss of motor neurons, a strong increase in plasma NfL levels, and demyelination^{162,169-171}. Neurodegeneration was assessed in this study by measuring plasma NfL. NfL concentrations were mildly reduced four weeks after treatment and strongly reduced nine weeks after AAV(L):bPGRN treatment in treated DKO mice compared to saline-treated DKO mice. However, lipid alterations related to myelin degradation, such as increased cholesterol esters and reduced galactosylceramide levels, were left almost unaffected by AAV(L):bPGRN, probably because of the severe neuronal loss that is still

much higher in treated DKO mice compared to WT. In order to draw definitive conclusions, a thorough analysis of myelin deficits, as previously done in the DKO mice, would have to be performed^{169,171}.

4.2.1.5. TDP-43 PATHOLOGY IS AMELIORATED BY AAV(L):bPGRN TREATMENT

A hallmark of FTLD-*GRN* is the presence of cytoplasmic TDP-43 and pTDP-43 inclusions³³. This phenotype is recapitulated in the DKO mouse models, as shown by immunoblot and immunofluorescence^{162,169,170}. In this study a robust increase of insoluble pTDP-43 was observed in DKO mice, which was reduced by 70% after AAV(L):bPGRN treatment. However, cytosolic TDP-43 inclusions, assessed *via* immunofluorescence against pTDP-43, were only observed sporadically in some animals and could therefore not be subjected to inferential statistics (data not shown). A potential explanation might be that the earlier endpoint of 15 weeks, chosen to avoid animal dropout, instead of terminating the animals at 18-20 weeks as done before, was too early to robustly detect pTDP-43 accumulation by immunofluorescence¹⁶⁹. Alternatively, these aggregates could be too sparsely distributed across the brain to be picked up robustly by immunofluorescence and whole-brain lysate analysis is necessary for quantifiable assessments. It should be noted that another study using the same mouse model showed consistent and quantifiable pTDP-43 immunofluorescence in the spinal cord of the DKO animals²³⁹. It is possible that the disease kinetics of this particular phenotype differ across regions of the CNS and that, while the brain at 15 weeks is, histologically, clear of pTDP-43, the more severely affected spinal cord will, at the same age, exhibit clear cytosolic inclusions.

Another readout that could potentially be used to test the efficacy of AAV(L):bPGRN in DKO mice is the investigation of cryptic exons or peptides^{64,65}. TDP-43 plays an important role in the post-transcriptional regulation of several proteins⁴¹⁻⁴³. Its nuclear depletion and the formation of cytosolic aggregates, as observed in FTLD-*GRN*, can lead to the missplicing of target genes, with the formation of cryptic exons and, if translated, cryptic peptides^{64,65}. The presence of insoluble pTDP-43 in the DKO model could already be indicative of TDP-43 mislocalization to the cytosol, which might in turn affect the splicing of its target genes. Preliminary experiments, however, could not identify splicing changes in the target gene *Sort1* (data not shown).

4.2.1.6. LIMITATIONS OF THE AAV(L):bPGRN DKO MOUSE STUDY

DKO mice made it possible to model FTLD-*GRN* and investigate the effects of AAV(L):bPGRN on several disease-relevant phenotypes. Almost all of these could be ameliorated upon AAV(L):bPGRN treatment, providing supporting evidence for brain-

penetrant PGRN replacement as a treatment approach for FTLD-*GRN*. Nevertheless, this study also presents several limitations.

First of all, by definition, the DKO model cannot be used to study the effect of therapeutics aiming at modulating endogenous PGRN levels, such as the anti-sortilin antibody. At the same time, a full knockout in homozygosity is necessary to assess FTLD-*GRN*-related phenotypes, since these are not observed in heterozygous mice and even a small remnant of PGRN will significantly delay the pathology^{125,127,170,251,252}.

Another important point is that the AAV(L):bPGRN treatment fails to achieve a full rescue of the pathological phenotypes. The constitutive loss of TMEM106B is an unlikely explanation, as TMEM106B KO mice present with much milder phenotypes compared to the *Grn* KOs and the DKOs^{160,162,169,170}. However, the timelines of treatment and tissue collection could explain these outcomes. An independent study, using direct CNS delivery of a PGRN-expressing AAV in DKO mice, compared two different treatment timepoints, six weeks of age – as in the study presented here – and also nine weeks of age²³⁹. While treatment at six weeks rescued most of the phenotypes in the spinal cord, treating nine-week-old mice resulted in consistently smaller beneficial effects. In fact, robust increases in CTSD, p62, and ubiquitin are already observed in two-month-old DKO mice, suggesting that deficits in protein degradation pathways arise early in disease²³⁹. Treatment as early as possible might therefore be necessary in order to prevent pathology altogether. Even so, plasma NfL levels, still roughly the same across treatment groups four weeks post injection, were robustly decreased at nine weeks in AAV(L):bPGRN-treated DKOs compared to untreated mice, suggesting a steep downward trajectory. AAV(L):bPGRN might thus not only slow down the progression of pathology, but even be able to revert it, to an extent. To validate this claim, however, later time points would also need to be analyzed in order to better trace the course of the disease.

4.2.2. A NOVEL hiPSC-DERIVED FTLD-*GRN* MODEL

Thanks to their modularity, hiPSCs are a useful tool to model disease and dissect pathomechanisms in a fully human *in vitro* system²⁵⁵. These cells can be differentiated into many different cell types and these can then be combined, as needed, to study specific cell-autonomous and intercellular interactions. This modularity is further expanded by the possibility to model the effect of disease-causing mutations. Patient-derived fibroblasts carrying pathogenic variants can be reprogrammed to hiPSCs, but also genome editing can be used to knock-in mutations or to generate a KO of disease-relevant genes²⁵⁶. Lastly, hiPSC models hold special significance in translational research, as their adaptability make them a perfect human *in vitro* system to test potential therapeutics. Given the therapeutic-oriented focus of the first study (3.1.), hiPSCs were a natural choice

to model FTL-*GRN* and to test the efficacy of PGRN replacement therapy using the brain-penetrant biotherapeutic PTV:PGRN.

Initially, a hiPSC line harboring a DKO of both, *GRN* and *TMEM106B*, similar to the mouse model used in this study, was generated using CRISPR/Cas9 genome editing. Based on initial experiments and considering the central role of neuroinflammation in FTL-*GRN*, hiPSC-derived DKO microglia and WT hiPSC-derived neurons were co-cultured for two weeks²⁵⁷. This co-culture model recapitulated multiple FTL-*GRN*-related pathologies. The protein levels and activity of several cathepsins more than doubled compared to WT co-cultures, indicating lysosomal dysfunction most likely in microglia. Importantly, both the processing of TDP-43 down to its 36 kDa and 25 kDa fragments, as well as its phosphorylation, both also observed in patients, were strongly increased^{31,45}. On top of that, this model exhibited neurodegeneration too, as the neuronal network was disrupted and the number of neurons decreased. All of these pathologies were ameliorated upon sustained treatment with PTV:PGRN.

4.2.2.1. LIMITATIONS OF THE hiPSC-DERIVED FTL-*GRN* MODEL

The hiPSC co-culture model presented in this study not only recapitulates hallmarks of FTL-*GRN* pathology, but it is further suitable for the assessment of the efficacy of novel therapeutics. However, this system also has some limitations.

TDP-43 mislocalization to the cytosol and the formation of aggregates could not be reliably observed by immunofluorescence or immunoblot. Longer co-cultures, aimed at enhancing TDP-43 pathology are also not possible, as in preliminary experiments this led to a complete neuronal loss. It could also not be ruled out that the processing of TDP-43 observed in co-cultures occurred in microglia after the engulfment of dead or dying neurons or neuronal processes. Excessive pruning was also observed both in *Grn* KO mice and, in the study presented in this thesis, the increased processing of the neuronal marker TUJ1 by DKO microglia is indicative of this²²⁹. In order to figure out whether TDP-43 processing and also the lysosomal hyperactivity take place in neurons or microglia, the co-cultures could have been sorted using magnetic activated cell sorting followed by the analysis of the two cellular fractions.

Furthermore, the rescue with PTV:PGRN was incomplete, similarly to the DKO mouse study. Cells were treated starting five days after the beginning of the co-cultures to mimic the treatment paradigm at six weeks of age, used in the DKO mouse model. In order to study whether PTV:PGRN might prevent altogether the FTL-*GRN*-like phenotypes observed *in vitro*, treatment could be started right at the beginning of the co-cultures or microglia could even be pre-treated and then plated along with the neurons.

Whether this model presents with other pathological hallmarks phenocopied by DKO mice and relevant to FTLD-*GRN*, such as autophagic defects and other indicators of lysosomal dysfunction, also remains to be investigated. Likewise, the microglial activation state was not analyzed in this study. Nevertheless, several studies investigated the cell-autonomous effect of single *GRN* KO in hiPSC-derived microglia^{133,231,258}. Transcriptome and proteome analysis showed, in these studies, a robust upregulation of lysosomal and microglial activation markers, such as lysosomal proteases, *CD68*, *APOE* or *TREM2*^{231,258}. In addition, both an increased recruitment of the lysosomal damage marker Galectin-3 to the lysosomal membrane, as well as the increase of the general lysosomal marker LAMP1 were observed¹³³.

Lastly, this study highlights the central role of microglia in the pathogenesis of FTLD-*GRN*, as the genetic modification of microglia alone was necessary and sufficient to generate pathology in neurons^{226,228,257}. However, as TDP-43 pathology primarily occurs in neurons, the cell-autonomous effect of a DKO in neurons should also be investigated. An intensive study of neuronal lysosomes in WT and *GRN* KO hiPSC-derived neurons described large-scale proteome alterations, increased lysosomal pH, and a decreased protease activity and overall protein turnover in *GRN*-deficient neurons¹³². Other studies showed very mildly increased levels of pTDP-43 and a minor cytosolic mislocalization of TDP-43 in *GRN* KO or in hiPSC-derived neurons from NCL patients^{259,260}.

4.3. LGMN – THE LINK BETWEEN *GRN* HAPLOINSUFFICIENCY AND TDP-43 PATHOLOGY?

In the second project presented in this thesis (3.2.), the hypothesis that LGMN is the link between *GRN* haploinsufficiency and TDP-43 pathology was investigated. Lysosomal dysfunction is a central hallmark of FTLD-*GRN*, especially since PGRN plays a variety of roles in lysosomal physiology^{3,249}. Loss of PGRN was shown to increase the expression and activity of lysosomal proteases not only in microglia, but also in other brain cell types^{125,126}. It thus seemed likely that a lysosomal protease might be involved in a downstream cascade resulting in TDP-43 processing and aggregation. This study focused on the lysosomal protease LGMN, as this enzyme was already shown to regulate the maturation of several cathepsins, as well as being capable of cleaving both PGRN and TDP-43^{115,175,176,181}.

LMGN protein levels and activity were shown to be increased in several biological systems that were analyzed in this study, including FTLD-*GRN* patient brains, hiPSC-derived *GRN* KO microglia, primary *Grn* KO murine microglia, and in the brain of *Grn* KO mice. Importantly, this increase was observed age-independently in *Grn* KO mice, while cathepsins only increased in aged animals, indicating that the higher LGMN levels are not just a byproduct of microgliosis-related lysosomal activation^{125,126}.

The reason for the increased LGMN levels might be a regulatory role of PGRN in LGMN activation, which is impaired by PGRN haploinsufficiency. This was assessed by co-incubation experiments of recombinant PGRN and LGMN. PGRN, but not the single granulins, was able to slow down autocatalytic LGMN maturation, but did not have an effect on already matured LGMN. Likewise, treatment of *Grn* KO mice with PTV:PGRN reduced LGMN protein levels and activity in the brain in a time-dependent manner. However, a direct interaction of the two proteins was not identified yet and it remains to be elucidated how exactly PGRN prevents the maturation of LGMN.

4.3.1. LGMN TRANSFER FROM MICROGLIA TO NEURONS

LGMN is highly expressed in microglia, but only very little is present in neurons (3.1.). However, TDP-43 pathology primarily occurs in neurons³³. Excess LGMN, as observed in FTLD-*GRN*, might therefore be transferred from microglia to neurons. To investigate this hypothesis, primary mouse hippocampal neurons were incubated with conditioned media collected from HeLa cells overexpressing LGMN. Inactive pro-LGMN was detected in the media and could be taken up by neurons. This is of importance, as mature LGMN would be denatured and thereby inactivated at neutral pH¹⁷². After the uptake, LGMN was matured and activated, and subsequently caused enhanced TDP-43 processing. This transfer hypothesis was further supported by hiPSC experiments. In a co-culture of hiPSC-derived *GRN* KO microglia and WT neurons, enhanced TDP-43 processing could be prevented by LGMN inhibition only in neurons by AAV-mediated overexpression of the cysteine-protease inhibitor cystatin F²⁶¹. This provided indirect evidence for a transfer of LGMN from microglia to neurons, as LGMN levels were much higher in microglia than in neurons and also *LGMN* transcripts were only upregulated in *GRN* KO microglia.

Nevertheless, the molecular details of the transfer mechanism were not addressed in this study. One possibility is the secretion of LGMN in exosomes. These small extracellular vesicles were shown to be important for intercellular communication in the brain and can contain various cargo proteins²⁶². By proteomics of isolated exosomes, LGMN and other lysosomal proteins were already shown to be present in exosomes of hiPSC-derived microglia²⁶³. Additionally, a robust increase in the expression of the exosome markers CD9 and CD81 was also observed in *GRN* KO hiPSC-derived microglia²³¹.

Another possibility is the formation of tunneling nanotubes as postulated for the transfer of alpha-synuclein between microglia²⁶⁴. Even the transport of whole mitochondria between microglia and neurons was shown to be possible through this mechanism²⁶⁵. Similarly, lysosomes or early endosomes might be transported between microglia or to neurons.

However, LGMN could be detected in the media of hiPSC-derived microglia (3.2.) and in the periphery, LGMN release was shown through the secretory pathway, where it was also found in the microenvironment of tumors^{172,266,267}. Taken together, a secretory mechanism, such as the transfer of exosomes, is a more likely scenario for the transfer of LGMN from microglia to neurons.

4.3.2. MODULATION OF LGMN INFLUENCES TDP-43 PATHOLOGY

TDP-43 pathology was described in form of enhanced TDP-43 processing in mouse embryonic fibroblasts (MEFs), hiPSC-derived microglia-neuron co-cultures, and in primary hippocampal mouse neurons incubated with LGMN-containing conditioned media (3.2.). As its nuclear localization sequence is lost during processing, cleaved TDP-43 is most likely mislocalized to the cytosol, enhances aggregation and is further found in intracellular neuronal aggregates in patients^{33,44}. Cleavage of TDP-43 is further necessary for the propagation of aggregates from cell to cell, highlighting excessive TDP-43 processing as a key disease-relevant mechanism²⁶⁸.

Whether LGMN is the protease responsible for the formation of TDP-43 fragments was first analyzed by KD in MEFs. The enhanced processing observed in *Grn* KO MEFs was diminished and there was even an enrichment of full-length TDP-43. Furthermore, Cystatin F-mediated blockage of neuronal cysteine proteases rescued the TDP-43 processing phenotype in hiPSC-derived neuron-microglia co-cultures. In addition, the specific inhibition of LGMN with a small molecule inhibitor in co-cultures of hiPSC-derived WT neurons with *GRN* KO microglia led to a size shift in the generated TDP-43 fragments, including an enrichment of the full-length form. However, this rescue was incomplete, as fragments were still formed, potentially by another lysosomal protease. In contrast, AAV-mediated overexpression of LGMN in the brain of *Grn* KO mice, led to the formation of aggregates containing processed and pTDP-43. Elevated LGMN further strongly raised plasma NfL levels and caused motor impairments similar to the ones observed in the *Grn* and *Tmem106b* DKO mouse model¹⁶⁹.

These findings strongly support a central role of LGMN in the pathological processing of TDP-43. This is further supported by the results of Herskowitz *et al.*, showing the presence of TDP-43 fragments with C-terminal asparagine residues in FTLD-*GRN* patient brains, as these would appear after cleavage by LGMN¹⁸¹. However, as LGMN directly influences the maturation of other lysosomal proteases, such as CTSL and CTSB, their downstream involvement in the pathogenesis cannot be excluded^{175,176}. Additionally, caspases were shown in the past to be able to cleave TDP-43 as well, but this was only shown *in vitro*²⁶⁹.

How LGMN-mediated processing of TDP-43 affects further downstream events, such as its nuclear depletion and the formation of cytosolic aggregates could not be addressed in this study, as the *Grn* KO models do not robustly have this phenotype. *Grn* KO mice only

show sparse and small aggregates at older ages^{125,130,228}. An alternative option to investigate the effect of LGMN inhibition on insoluble TDP-43 aggregates containing pTDP-43 *in vivo* could be the treatment of the DKO mouse line with the small molecule LGMN inhibitor or the introduction of an additional KO of *Lgmn*. This would also enable the characterization of the effects of LGMN on other disease-relevant phenotypes, such as neurodegeneration, microglial hyperactivation, and motor impairment.

4.3.2.1. WHERE DO LGMN AND TDP-43 INTERACT?

Pro-LGMN, after being transferred from microglia to neurons, needs to be activated and then has to interact with TDP-43 to enable its processing. However, TDP-43 is a nuclear protein and LGMN a lysosomal protease that is only active at acidic pH, creating an apparent spatial paradox¹⁷². Despite its general localization to the nucleus, TDP-43 shuttles between the nucleus and the cytosol in homeostasis, as part of its RNA-regulating role²⁷⁰. Under stress conditions, such as enhanced oxidative stress, endoplasmic reticulum stress, or impaired protein degradation, TDP-43 was shown to be mislocalized to the cytosol and to form aggregates²⁷¹⁻²⁷³. Excess amounts of TDP-43 could then be labeled by ubiquitin for proteasome-mediated degradation or directed towards the autophagic pathway and subsequently lysosomal degradation^{33,274-276}. In the lysosome, TDP-43 could then be processed by LGMN and its fragments released into the cytosol, as the lysosomal membrane was reported to be damaged in PGRN deficiency¹³³. Likewise, LGMN could escape from the lysosomes. As lysosomal pH is increased upon loss of PGRN, LGMN might not be able to undergo complete maturation and, while mature LGMN is unstable at neutral pH, its intermediate form was reported to be able to be stabilized at neutral pH^{172,173}. Although stochastically unlikely, it could then process TDP-43 in the acidic microenvironment close to leaky lysosomes.

In this study, some evidence is provided for the direct interaction of LGMN and TDP-43 (3.2.). In *Grn* KO MEFs, cytosolic TDP-43 co-localized with LGMN and the lysosomal marker LAMP1, in close proximity to the nucleus. This supports the possibility of lysosomal processing of TDP-43 by LGMN. Additionally, patches positive for TDP-43, LGMN, and DAPI, but not LAMP1, were also observed in the close proximity of the nucleus. These might be stress granules or liquid-liquid-phase-separated membrane-less organelles, which would require additional investigation⁵⁴.

4.4. THE ROLE OF CELLULAR CROSSTALK IN FTLD-GRN

The pronounced role of LGMN in FTLD-GRN pathogenesis highlights the importance of cellular crosstalk as a fundamental mechanism underlying FTLD-GRN and neurodegeneration in general. In this study, it is shown that LGMN, highly expressed in

Discussion

microglia and upregulated upon PGRN deficiency, can potentially be shuttled from microglia to neurons, where it contributes to TDP-43 pathology by enhanced processing of the protein (3.2.). Similarly, the DKO of *GRN* and *TMEM106B* in hiPSC-derived microglia was necessary and sufficient to induce TDP-43 pathology and neurodegeneration in WT neurons in a co-culture setting (3.1.). Both findings position microglia at the center of pathobiology. Microglia are highly dynamic cells which rapidly react to changes in their environment¹. An internal disruption of their lysosomal function might therefore trigger their transition to the DAM state, as described in aged *Grn* KO mice and hiPSC-derived *GRN* KO microglia^{226,228,231}. It was further shown that an initial lysosomal dysfunction in microglia eventually induces similar effects in other CNS cell types¹²⁶.

Microglial activation also leads to the release of pro-inflammatory cytokines, such as TNF and IL-6, which can create a toxic environment for neurons, which was also observed in PGRN-deficient mice²³⁰. Lui *et al.* further demonstrated that microglia in *Grn* KO mice and FTLD-*GRN* patients have increased expression of the complement factors C1q and C3, resulting in enhanced synaptic pruning²²⁹. These complement factors have been shown before to be critical for the removal of excess synapses during development¹⁹³. However, a follow-up study by Zhang *et al.* investigated mechanistically the consequences of complement upregulation upon PGRN deficiency by incubating primary neurons with conditioned media from either WT or *Grn* KO microglia²²⁸. The increase of C1q and C3 in *Grn* KO primary microglia and their media was confirmed and resulted in increased cytosolic accumulation of TDP-43 and neuronal cell death, which could be reversed by the genetic ablation of these complement factors. Whether LGMN can directly contribute to the microglial release of complement components could be analyzed by studying the secretome of *GRN* and *LGMN* DKO microglia or *GRN* KO microglia treated with a LGMN inhibitor. Evidence supporting an indirect contribution of LGMN was shown in the context of T-cell activation, where CTSL, a lysosomal protease regulated by LGMN, was involved in the processing of C3 into its active fragments C3a and C3b²⁷⁷. Alternatively, it is also likely that complement activation is a direct consequence of the lysosomal dysfunction, as increased complement levels were also reported in the lysosomal storage disorders Gaucher disease and Niemann-Pick disease^{278,279}.

Another recent publication postulates a direct involvement of astrocytes in the pathogenesis of FTLD-*GRN*²⁵⁹. De Majo *et al.* analyzed three-dimensional hiPSC-derived neuronal WT and *GRN* KO cultures with or without WT or *GRN* KO hiPSC-derived astrocytes. Culturing neurons in the presence of *GRN* KO astrocytes resulted in increased levels of cytosolic TDP-43, as well as an increased expression of cryptic STMN2, which could be reversed by supplementation of recombinant PGRN. Even though the study remains descriptive, astrocytes may have an impact on neuronal pathology in FTLD-*GRN*. Whether these effects could be potentiated by using a tri-culture system, including microglia, would be an interesting question to address.

Taken together, cellular cross-talk, especially between microglia and neurons, plays a critical role in the pathogenesis of FTLD-*GRN*. However, the modulation of microglial hyperactivation, for example by inhibition of TREM2 signaling using antagonistic antibodies, might be a double-edged sword, as it was shown to mitigate the expression of DAM genes in *GRN* KO models, but at the same time it failed to rescue lysosomal pathology and even strongly increased neurodegeneration²³¹.

4.5. SUMMARY

In summary, the two studies presented in this thesis aimed at deepening the understanding of the molecular mechanisms underlying FTLD-*GRN* and leveraging this knowledge for the development of potential disease-modifying therapeutics.

In the first study, AAV(L):bPGRN was assessed as a complementary treatment approach to recombinant PTV:PGRN, combining the advantages of gene therapy and the ease of the peripheral administration of a brain-penetrant biotherapeutic. Using this treatment paradigm, PGRN levels in the brain could be increased after a single injection without any toxic side effects. All the phenotypes characteristic of the DKO mice were corrected or ameliorated by AAV(L):bPGRN administration, including their brain lipidomic and transcriptomic profiles, which were characterized *de novo* in this study. This also strengthens the applicability of DKO mice as a model of FTLD-*GRN* and their use for the evaluation of therapeutic strategies. Using hiPSC-derived co-cultures of WT neurons and DKO microglia, a novel cellular model of FTLD-*GRN* pathology was established and characterized. Neuron-microglia co-cultures recapitulate the cellular phenotypes of the DKO mice *in vitro*, showing lysosomal hyperactivation, TDP-43 pathology, and neurodegeneration. Once again, these phenotypes could be ameliorated by PGRN replacement making it a useful system for the investigation of FTLD-*GRN*-associated disease mechanisms and to screen therapeutic approaches. In conclusion, both the *in vitro* and *in vivo* DKO are *bona fide* FTLD-*GRN* models, which not only present with disease-relevant phenotypes, but can also be valuable in translational research. In addition, PGRN replacement therapy using brain-penetrant biotherapeutics, such as AAV(L):bPGRN or PTV:PGRN, is a promising approach for the treatment of FTLD-*GRN*.

The second, more mechanistic, study investigated LGMN as the potential link between PGRN haploinsufficiency and TDP-43 pathology. PGRN was shown to regulate the maturation of LGMN and consequently, LGMN levels were found to be increased in various models of PGRN deficiency and in FTLD-*GRN* patient brains. The study further provides evidence for a transfer of LGMN from microglia to neurons, where it could be activated and ultimately process TDP-43 into its disease-associated fragments. The specific role of LGMN in this cascade of events was confirmed by using a combination of

Discussion

Lgmn KD, a cysteine-protease inhibitor, a specific small molecule LGMN inhibitor, and AAV-mediated LGMN overexpression in the mouse brain. Taken together, these results prove that LGMN is an important link between loss of PGRN and TDP-43 pathology, however, both its transfer mechanism from microglia to neurons and the subcellular compartment in which its interaction with TDP-43 occurs still need further investigation.

5. OUTLOOK

The studies presented in this thesis investigate both the feasibility of PGRN replacement therapy as a treatment strategy for FTLD-GRN as well as the role of LGMN as a link between PGRN deficiency and TDP-43 pathology. Nevertheless, some related open questions remain, which will be briefly discussed here.

Could additional readouts for TDP-43 pathology be assessed to evaluate the efficacy of PGRN replacement in the DKO mouse model?

TDP-43 pathology was robustly detected as insoluble pTDP-43-positive aggregates by immunoblot. However, the presence of cytosolic mislocalization could not be demonstrated by immunofluorescence, due to a sparse fluorescent signal distribution and a high variability across animals. As this readout was shown to be robust in the spinal cord of DKO mice in an independent study²³⁹, characterizing the pathology in the spinal cords of the AAV(L):bPGRN-treated mice would provide insights into the potential effects of PGRN replacement therapy on TDP-43 mislocalization. In addition, it could also be tested whether cryptic exons, a functional consequence of the nuclear loss of TDP-43, are present in this model.

What is the pathological sequence in FTLD-GRN?

Several studies have already aimed at addressing this question in cellular systems, *Grn* KO mice, and FTLD-GRN patient cohorts and lysosomal dysfunction was reliably identified as a trigger of pathology. For a more detailed analysis of the order in which the different pathological manifestations arise, the DKO mouse model is ideally suited. It presents with a lot of strong disease-relevant phenotypes and has a fast disease progression. To answer this question, different timepoints could be analyzed to dissect the dynamic nature of pathology, as it was done in the first study presented in this thesis for rotarod performance and plasma NfL levels.

What is the effect of the single or combinatorial loss of PGRN and TMEM106B on the crosstalk between microglia and neurons?

In the projects presented in this thesis it was shown how *GRN* KO and DKO hiPSC-derived microglia can cause different pathologies in neurons. By applying hiPSCs, the possibility exists to investigate all different kinds of genetic and cell type combinations. In order to shed light on the interaction of PGRN and TMEM106B, the proteome and secretome of WT, *GRN* KO, *TMEM106B* KO, and DKO hiPSC-derived microglia and neurons in either monoculture or co-culture could be analyzed by proteomics. This would make it possible to elucidate the cell-autonomous and non-cell-autonomous contributions of the respective loss of the two proteins and their consequences on the global protein expression and secretion profiles. Potential hits could then be validated in targeted mechanistic studies.

How is LGMN shuttled from microglia to neurons?

This question was partly addressed in the second project presented in this thesis. LGMN from conditioned media could be taken up by neurons and *GRN* KO hiPSC-derived co-cultures released more LGMN into the media. A transfer through vesicles, most likely exosomes, is likely, but should be verified experimentally. Exosomes from WT and *GRN* KO hiPSC-derived microglia may be purified and their cargo analyzed by LGMN ELISA or immunoblot. If LGMN was to be found in exosomes, purified exosomes could also be fluorescently labeled and supplemented to neuronal cultures in order to study potential uptake mechanisms. Another possibility is the generation of a hiPSC line expressing endogenously tagged LGMN. Microglia differentiated from such a hiPSC line could then be co-cultured with WT neurons to investigate the transfer mechanism. In addition, to confirm that LGMN is indeed shuttled from microglia to neurons, *LGMN* KO hiPSC lines could also be generated to exclude the possibility that the enhanced TDP-43 pathology in neurons results from an upregulation of neuronal LGMN upon co-culture with microglia.

Where do LGMN and TDP-43 meet in neurons?

The lysosomal protease LGMN and the nuclear protein TDP-43 have to meet in some subcellular compartment in order for LGMN to process TDP-43. In MEFs, the co-localization of LGMN and TDP-43 in LAMP1-positive lysosomes could already be shown, as well as in LGMN-, TDP-43-, and DAPI-positive patches in the cell. The exact localization should be further confirmed and detailed *via* super resolution microscopy, also to address whether TDP-43 and LGMN co-localize outside of lysosomes, at their membrane or in their lumen. Ideally, this would then be translated to neurons, where neurons from the experiments discussed in the previous question could be analyzed for co-localization of internalized LGMN and TDP-43.

6. ACKNOWLEDGEMENTS

At this point, I would like to thank everyone who helped me during my PhD journey.

First, I want to thank **Prof. Christian Haass** for welcoming me into his laboratory and giving me the opportunity to work on such intriguing projects during my PhD. I am grateful for his continuous support and guidance. Most importantly I want to thank him for his mentorship and professional advice, and for providing many opportunities to develop as a person and scientist.

I would like to further thank **Dr. Anja Capell** for providing direct supervision in the laboratory. I truly appreciate our many discussions, the experimental advice and that she was always available when I needed help.

Furthermore, I want to thank **Prof. Dominik Paquet**, not only for hosting me in his laboratory for the hiPSC work, but also for welcoming me as a part of his team and providing valuable scientific input and support.

I want to thank the members of my thesis advisory committee, namely **Prof. Christian Haass, Prof. Dominik Paquet, Prof. Paul Saftig** and **Dr. Anja Capell**, for the many good discussions we had and all the valuable input and help that I received.

Besides, I am very grateful to all the people that taught me new methods and always had the necessary patience. Here, I want to especially thank **Dr. Anja Capell, Dr. Georg Werner, Dr. Anika Reifschneider, Katrin Buschmann, Dr. Sophie Robinson, Dennis Crusius, Dr. Xianyuan Xiang, Dr. Jane Hettinger, Dr. Ida Pesämaa, Dr. Astrid Feiten, Dr. Iñaki Paris, Dr. Lena Spieth, Dr. Stefan Berghoff** and **Lennart Schlaphoff**.

I also want to thank all the people that continuously supported me with my projects through technical support. This especially includes **Katrin Buschmann, Ramona Rodde** and **Claudia Thiel**.

A special thanks goes to my students **Christian Schrader, Bea Polke** and **Kyle Brandon**. It was a pleasure working with them and I greatly enjoyed supervising them and to see them grow as scientists. I also want to thank my HiWi **Mariana Martins** for her great support in the last stretches of the PhD.

I further want to thank all the people that were involved in the work that led to the two manuscripts presented in this thesis. Without them, this would not have been possible. A special thanks goes to my co-starred authors **Dr. Matt Simon, Dr. Sophie Robinson** and **Maria Mühlhofer** for greatly contributing to the work as well as to **Prof. Christian Haass, Dr. Anja Capell, Dr. Gil Di Paolo** and **Prof. Dominik Paquet** for their supervision.

Acknowledgements

I would like to thank all the **collaborators at Denali** for this very fruitful collaboration, and for providing the opportunity to visit for an internship. Particularly, I would like to thank **Dr. Jung Suh and his team** for being great and fun teachers and colleagues and **Dr. Gil Di Paolo** for welcoming me into his team as well. I would also like to thank **Dr. Joe Lewcock** for making the internship possible and **all Denalians** for being so welcoming.

On top of that, I want to thank all the people at the **institute and my labs** for creating an inspiring environment with many good discussions, seminars and fun events. Importantly, I want to thank all the people in the lab and at the institute who welcomed me with kindness and continuously provided moral support throughout this not always smooth journey. They were not only **great colleagues**, but also became friends along the way.

Lastly, I want to thank **all my friends and my brother**, who supported me throughout the whole PhD journey and made every setback and issue more bearable and the successes worth celebrating.

8. CURRICULUM VITAE

Marvin Reich

HIGHER EDUCATION

- 10/2020 – present *Ludwig Maximilian University of Munich (Munich, Germany)*
PhD Student at the Graduate School of Systemic Neurosciences
- 04/2016 – 01/2020 *University of Konstanz (Konstanz, Germany)*
Master of Science (with distinction)
 Thesis: Characterization of hiPSC-derived microglia towards an application in compound testing and screening
- 08/2016 – 06/2017 *Uppsala University (Uppsala, Sweden)*
Erasmus+ scholarship
- 10/2012 – 03/2016 *University of Konstanz (Konstanz, Germany)*
Bachelor of Science
 Thesis: Engineering of the KOD DNA-Polymerase for epigenetic applications

RESEARCH EXPERIENCE

- 06/2023 – 07/2023 *Denali Therapeutics (South San Francisco, California, USA)*
PhD Internship in the OMX department
 Project: Lipidomics cross-comparison of different lysosomal impairment models
General introduction to LC/MS planning, execution, and analysis – Comparison between datasets of different FTD and NPC models
- 03/2020 – present *German Center for Neurodegenerative Diseases & Ludwig Maximilian University of Munich (Munich, Germany)*
PhD Thesis in the laboratory of Prof. Dr. Dr. h.c. Christian Haass
 Project: Rescue of FTD-GRN via a brain-penetrant biotherapeutic
Development of a hiPSC-based model for FTD-GRN – Testing a therapeutic approach to treat the hiPSC-based model and a mouse model for FTD-GRN – Investigating neuron-microglia crosstalk in the hiPSC-based model
- 04/2019 – 12/2019 *F. Hoffmann - La Roche Ltd. (Basel, Switzerland)*
Master's Thesis in Neuroscience Discovery and the Stem Cell Group
 Project: Characterization of hiPSC-derived microglia towards an application in compound testing and screening
Development of a protocol to generate hiPSC-derived microglia – Functional, genetic, and morphological characterization of the model – Application of the model to study the role of the microglial receptor TREM2
- 11/2018 – 12/2018 *University of Konstanz (Konstanz, Germany)*
Intensive Course in Immunology in the laboratory of Prof. Dr. Marcus Groettrup
 Project: 26S proteasome interaction partners and its specific activation by the ubiquitin-like protein family
Synthesis and purification of the 26S proteasome – Binding and activation analysis of potential interactors
- 08/2018 – 10/2018 *Swiss Federal Institute of Technology Zurich (Basel, Switzerland)*
Internship in the Bio Engineering Laboratory of Prof. Dr. Andreas Hierlemann
 Project: Investigation of the prenatal development of neuronal networks using murine cerebral organoids
Establishment of a multielectrode array setup for organoids – Longitudinal recordings of murine organoids
- 11/2017 – 07/2018 *F. Hoffmann - La Roche Ltd. (Basel, Switzerland)*
Internship in Neuroscience Discovery and Mechanistic Safety
 Project: Alpha-synuclein preformed fibril (PFF)-induced toxicity in a human neuronal cell model
Setup of LUHMES neuronal cell differentiation – Study of PFF-induced cellular and mitochondrial toxicity
- 04/2016 – 06/2016 *University of Konstanz (Konstanz, Germany)*
Intensive Course in Biochemical Pharmacology in the laboratory of Prof. Dr. Thomas Brunner
 Project: Investigation of kinetics and synergistic effects of mediators of different apoptosis pathways
Live-cell imaging and immunoblotting to dissect the time-resolved apoptosis induction by cisplatin and TRAIL
- 07/2015 – 10/2015 *University of Konstanz (Konstanz, Germany)*
Bachelor's Thesis in the laboratory of Prof. Dr. Andreas Marx
 Project: Engineering of the KOD DNA-Polymerase for epigenetic applications
KOD DNA-polymerase mutagenesis via error-prone PCR – Study of the effect of mutations on polymerase selectivity

CONFERENCE PRESENTATIONS

Talks

Rescue of FTD-GRN Pathology via Peripheral AAV-mediated Delivery of a Brain-Penetrant PGRN Biologic

International Conference on Alzheimer's and Parkinson's Diseases and related neurological disorders in Lisbon, Portugal (03/2024)

Eibsee Meeting: Cellular Mechanisms of Neurodegeneration in Grainau, Germany (12/2023)

Keystone Symposium on Neuroimmune Interactions: From Basic Mechanisms to Novel Therapeutic Directions in Whistler, Canada (05/2023)

Neuron-microglia crosstalk in a human iPSC-based FTD model

Keystone Symposium on Neuro-Immune Interactions in the Central Nervous System in Keystone, Colorado, USA (06/2022)

Posters

Rescue of FTD-GRN Pathology via Peripheral AAV-mediated Delivery of a Brain-Penetrant PGRN Biologic

Eibsee Meeting: Cellular Mechanisms of Neurodegeneration in Grainau, Germany (12/2023)

Keystone Symposium on Neuroimmune Interactions: From Basic Mechanisms to Novel Therapeutic Directions in Whistler, Canada (05/2023)

Rescue of FTD-GRN via a brain penetrant biotherapeutic

Eibsee Meeting: Cellular Mechanisms of Neurodegeneration in Grainau, Germany (10/2022)

Retreat of the Graduate School of Systemic Neurosciences in Garmisch-Partenkirchen, Germany (10/2022)

Neuron-microglia crosstalk in a human iPSC-based FTD model

Retreat of the Institute for Stroke and Dementia Research in Herrsching, Germany (07/2022)

Keystone Symposium on Neuro-Immune Interactions in the Central Nervous System in Keystone, Colorado, USA (06/2022)

Human iPSC-derived microglia as a model system to investigate TREM2 biology

100 Years of Microglia Symposium in Lausanne, Switzerland (12/2019)

Eibsee Meeting: Cellular Mechanisms of Neurodegeneration in Grainau, Germany (11/2019)

GRANTS AND AWARDS

06/2022	Graduate School of Systemic Neurosciences Travel Grant
02/2022	NanoString nCounter Gene Expression Grant
12/2019	Honorable Mention: Poster Session of the 100 Years of Microglia Symposium in Lausanne, Switzerland

MEMBERSHIPS AND LEADERSHIP

05/2023 – present	Member of the German Stem Cell Network
04/2023 – present	PhD representative at the DZNE Munich
11/2021 – present	PhD representative at the Department of Metabolic Biochemistry (Head: Prof. Dr. Dr. h.c. Christian Haass)
08/2021 – present	Coordinator of the Haass lab hiPSC facility
01/2014 – present	Member of the German Association of Biochemistry and Molecular Biology

TEACHING

11/2022 – 10/2023	Supervision of a Master's student internship and thesis
06/2022	Medical student seminar on the biochemistry of Alzheimer's disease
02/2022 – 11/2022	Supervision of a Master's student internship and thesis
07/2021 – 09/2021	Supervision of a Master's student internship
04/2018	Supervision of a high school student for their practical internship

ADDITIONAL SKILLS

Languages

German (native); English (fluent); French, Swedish (moderate)

IT Skills

Microsoft Office (advanced); ImageJ, GraphPad Prism, Adobe Illustrator, LaTeX (proficient); MATLAB, Python (basic)

Soft Skill Trainings

Unconscious bias; Psychological safety; Efficiency; Leadership

9. LIST OF PUBLICATIONS

Robinson S*, **Reich M***, Mühlhofer M*, Buschmann K, Wauters E, Mühlhofer Q, Werner G, Ahles A, Engelhardt S, Krenner C, Bartels B, Gutbier S, Reifschneider A, Riemenschneider H, Reinheckel T, Edbauer D, Simon MJ, Kariolis MS, Logan T, Di Paolo G, van Broeckhoven C, Damme M, Paquet D, Haass C#, Capell A#. Enhanced legumain activity links progranulin deficiency to TDP-43 pathology in frontotemporal lobar degeneration. In revision at Nature Neuroscience.

Reich M*, Simon MJ*, Polke B, Werner G, Schrader C, Paris I, Robinson S, Suh JH, Sandmann T, Schlaphoff L, Spieth L, Berghoff S, Logan T, Nuscher B, Buschmann K, Simons M, Kariolis MS, DeVos SL, Lewcock JW, Paquet D#, Capell A#, Di Paolo G#, Haass C#. Rescue of FTLD-associated TDP-43 pathology and neurodegeneration by peripheral AAV-mediated expression of brain-penetrant progranulin. In revision at Science Translational Medicine.

10. EIDESSTATTLICHE VERSICHERUNG/AFFIDAVIT

Marvin Reich
(Studierende / Student)

Hiermit versichere ich an Eides statt, dass ich die vorliegende Dissertation

Neuron-Microglia Crosstalk in FTLD-GRN models

selbstständig angefertigt habe, mich außer der angegebenen keiner weiteren Hilfsmittel bedient und alle Erkenntnisse, die aus dem Schrifttum ganz oder annähernd übernommen sind, als solche kenntlich gemacht und nach ihrer Herkunft unter Bezeichnung der Fundstelle einzeln nachgewiesen habe.

I hereby confirm that the dissertation is the result of my own work and that I have only used sources or materials listed and specified in the dissertation.
