Zusammenfassung

Die vorliegende Arbeit *“Suche nach Cepheid-artigen Veränderlichen Sternen in nördlichen Zwerggalaxien der Lokalen Gruppe”* faßt die Ergebnisse des *VarStarDwarves*-Projektes für alle “blauen”, periodisch Variablen Sterne (VS) zusammen. Die Zielsetzung des *VarStarDwarves*-Projekts, das seit 1999 an der Universitäts-Sternwarte München betrieben wird, läßt sich am besten durch ein Zitat aus dem zugrundeliegenden DFG-Antrag (Ho1812) erläutern: “Die Bestimmung der Sternentstehungsgeschichte von Zwerggalaxien (ZG) erlaubt, wesentliche Randbedingungen für die Modelle der Evolution von Galaxien abzuleiten. Eine Grundvoraussetzung hierzu ist die Kenntnis der genauen Distanz der ZG. Die Beobachtung hinreichend großer Sample von Veränderlichen Sternen ermöglicht es, diese Distanzen wesentlich präziser als bisher zu bestimmen. Um diese großen Sample zu erhalten, sollen mit für Microlensing entwickelten Bildverarbeitungs-methoden VS in nahen ZG bis weit unter die bis jetzt erreichten Detektionsgrenzen nachgewiesen werden. Darüberhinaus werden die gefundenen VS auch Hinweise zur stellaren Zusammensetzung und damit zum Entwicklungszustand der ZG geben.” Die Ergebnisse für langperiodische, “rote” VS wurden bereits in der Arbeit von Snigula [2006] präsentiert.

Im Rahmen des *VarStarDwarves*-Projekts wurden umfangreiche Modernisierungen und Verbesserungen an den Beobachtungsinstrumenten und dem Umfeld des Observatoriums Wendelstein durchgeführt und darüberhinaus die Entwicklung und der Bau einer neuen, modernen Zweikanal-CCD-Kamera initiiert. Auch diese Aspekte werden hier dokumentiert und die erreichten Fortschritte aufgezeigt (siehe hierzu Kapitel 2.2, 2.3 und 3 sowie die Anhänge A bis C). Diese Dissertation untergliedert sich weiter in eine Einleitung, die neben einer kurzen Vorstellung der mit dem Projekt befaßten Kollegen und ihrer diesbezüglichen Aufgabenbereichen v.a. eine historische Einführung in die Gebiete der Lokalen Zwerggalaxien sowie der “blauen” pulsationsveränderlichen Sterne bietet (Kap. 1), einen Überblick über Kandidatenauswahl und die durchgeführten Beobachtungen (Kap. 2.1, 2.4 und 2.5), sowie eine detaillierte Erläuterung der aufwendigen, z.T. ebenfalls im Rahmen des Projekts entwickelten Datenanalyseverfahren (Kap. 4). Die wesentlichen wissenschaftlichen Ergebnisse der Arbeit sind neue, unabhängige Entfernungsbestimmungen mittels δ Cephei Perioden-Leuchtkraftbeziehungen zu zwei der sechs *VarStarDwarves* Zwerge, die Bestätigung der Entfernung eines weiteren Zwergs, sowie die Entdeckung etlicher weiterer VS-Kandidaten, deren endgültige Bedeutungen erst durch weitere Beobachtungen bestimmt werden können, wobei aber durchaus mit weitreichenden Konsequenzen für das physikalische Verständnis der entsprechenden VS oder ihrer “Muttergalaxie” zu rechnen ist (Kap. 5).

Chapter 1

Introduction

1.1 The *VarStarDwarves* Project – Motivation and Context

This work here is one of two PhD theses summarising the results of the *VarStarDwarves* project (supported by DFG grant Ho1812 and Ho1813). In order to give an overview on the project goals I will quote the formal application for the DFG grant:

“The determination of the stellar evolution of dwarf galaxies (DG) allows to derive constraints on models of galaxy evolution. One basic requirement is information on the exact distance of the DG. The observation of adequate samples of variable stars (VS) provides the means of improving present distance determinations. To collect those samples we will apply image processing methods which were developed for micro lensing studies to detect VS in nearby DG far beyond current limits. In addition all VS found will indicate the DG stellar content and therefore its evolutionary state. [...]”

The first thesis [Snigula, 2006] presented the results on red Long Period Variables (LPV), i.e. Mirae stars, which are pulsating Asymptotic Giant Branch (AGB) stars. This thesis here will present the results on the shorter period pulsating stars, i.e. classical and Type II δ Cephei stars. The *VarStarDwarves* project also involved the development of a new two-channel CCD camera as well as many upgrades (mostly software) to the existing telescope and CCD camera which are reported in these two theses.

1.2 Overview – The People Involved

The *VarStarDwarves* project involved many people and since it will not be reported elsewhere I will summarise here who did what in the context of the project. The project was started by Ralf Bender, Ulrich Hopp, and Heinz Barwig, the latter two applying for the DFG grants which successively supported me and Jan Snigula. We were both assiduous enough to be rewarded with full positions soon in the course of the project. Ralf Bender was/is the thesis advisor for the two theses originating from the project. The purely technical part of the project involved the building of a new CCD camera for Wendelstein observatory [see Chap. 3 and Goessl et al., 2003] and improvements to the existing observatory infrastructure, its telescope and the current

CCD camera [see Sect. 2.2 and Snigula, 2006]. While I was responsible for the optical design as well as the mechanical draft, and for most of the final mechanical assembling, Wolfgang Mitsch, the electronics engineer for Wendelstein observatory, provided advice in all of these and did everything which involved electronics for the new camera. The complete mechanical design was elaborated by Werner Altmann, an external contractor. Most of the mechanical parts have been manufactured by the USM workshop (Franz Mittermaier and Peter Well). The camera software again was mostly developed by me. I wrote the routines for the motor controller which operates the shutters and the filter sliders and also implemented the camera daemon which provides high level functions for the camera control utilising the daemon model written by Jan Snigula for the WST 80 cm telescope remote control. The graphical user interface (GUI) for the camera was built by Johannes Koppenhöfer and me. All improvements to the observatory infrastructure which involved “switches and wires” were made by Wolfgang Mitsch. While I added many features to the current CCD camera software Jan Snigula provided a remote control daemon and GUIs for the 80 cm telescope. Together we also developed a more reliable software for auto-guiding from scratch (Jan GUI, me daemon).

Until the end of 2005 there have been about 650 nights on Wendelstein and 70 nights at Calar Alto which produced, among others, also observations for the project. Most of the observations were done by USM staff observers, Christoph Ries (46%) and Otto Bärnbantner (15%). Me (13%), Jan Snigula (9%), Silona Wilke (6%), and Arno Riffeser (4%) as well as some occasional observers did the rest. (See Sect. 2.5 and Tab. 2.3).

The preliminary visual inspection of about 37000 raw images as well as the necessary sorting, book keeping and archiving was exclusively done by myself. For 15% of the repeated inspection of the raw reduced images for positional registration I had the help of a student, Silona Wilke.

Together with the “coders” from the WeCAPP [Riffeser et al., 2001] and MUNICS [Drory et al., 2001] team we developed a shell command line oriented image processing and data reduction software. The pipeline relies on a high performance C++ array calculations- and I/O-library LTL [Gössl et al., 2004]: Niv Drory did the conceptional design on it learning from the Blitz++ library [Veldhuizen, 1995]. He also implemented the dynamical arrays and parts of the linear algebra, while I did the other part of the latter, the statistical functions and FITS¹ file I/O. Jan Snigula finally added ASCII file I/O, and Arno Riffeser did extensive testing of the library. The pipeline itself consists of several parts: Firstly, a “standard reduction” part (FITSTools, see Sect. 4.2), implemented by me with support and ideas of Arno Riffeser, and the difference imaging² and PSF fitting photometry (MuPipe, see Sect. 4.3) by Arno Riffeser [Gössl and Riffeser, 2002, 2003]. Jan Snigula provided the absolute photometric calibration combining DAOPHOT [Stetson, 1987] photometry of our reference images by Ulrich Hopp with HST photometry [Holtzman et al., 2006] as well as with standard star observations of the Calar Alto data set. [See Sect. 4.4.2 and Snigula, 2006, Chap. 3.] I again did the variability detection and implemented a Lomb [Lomb, 1976, Scargle, 1982] period analysis for the “shorter” periods while Jan Snigula produced a Lafler-Kinman period computation [Lafler and Kinman, 1965] for the “longer” periods and the visualisation by Yorick [Munro, 1995] routines. [See Sect. 4.6 and

¹The Flexible Image Transport System, see Wells et al. [1981].

²An elaborated version of optimal image subtraction (OIS) originally conceived by Alard and Lupton [1998].

Snigula, 2006, Chap. 4.] Completeness simulations finally were mostly implemented by Jan except for the Lomb completeness which was coded by me. [See Sect. 4.6.3 and Snigula, 2006, Chap. 5.]

As can be seen by the long list of prerequisites above it has been a long way before we finally could work our way through to actual science. While Jan Snigula worked on the LPV / AGB stars I concentrated on all types of Cepheid variables. Ulrich Hopp provided advice and controlling as he did for the whole project.

1.3 The Local Group of Galaxies

The Local Group (LG) of galaxies³ is dominated by two major Spiral Galaxies, our Milky Way Galaxy (MWG) and the Andromeda “Nebula” (M 31)⁴. Actually, membership to the LG can be defined by being bound to their combined gravitational potential⁵. Next in size is the Triangulum Galaxy (M 33)⁶, a minor bulge-free Spiral and maybe close enough to be bound to M 31, followed by two Irregular galaxies, the Large and the Small Magellanic Clouds (LMC and SMC)⁷, which are the most massive satellites of the MWG. After M 32 has been discovered by Gentil de la Galazière [1765], \approx 40 LG galaxies have been found until now, most of them in the last decades, and there probably still remain in the order of 10 to 20 LG members undiscovered [Mateo, 1998, Grebel, 1999]. All those LG members or member candidates are Dwarf Galaxies (DGs)⁸. Fig. 1.1 and Tab. 1.1 give a census of the LG at the beginning of the *VarStarDwarves* project while Tab. 2.1 in Sec. 2.1 details the selections criteria of the *VarStarDwarves* candidates.

The LGDs were classically divided into dwarf ellipticals (dEs), dwarf spheroidals (dSphs), and dwarf irregulars (dIrrs), but at a closer look this classification scheme now seems to be artificial [Grebel, 1999]: The dEs are compact with dense cores and contain mainly old and intermediate age populations. DSphs follow the same scaling relation as dEs [Ferguson and Binggeli, 1994] but have no dense cores and are in fact the faintest and least massive galaxies of all. They have little or no gas and also no recent star formation. Both former types are usually found near more massive galaxies, while the dIrrs tend to reside in more isolated regions. DIrrs are similar to dSphs, but host ionised gas and have recent or ongoing star formation in addition to underlying older populations. There is no strong dichotomy between the LGDs, there are rather ample transient types. Even more, they “*were found to vary widely in their star formation histories,*

³As depicted by Hubble [1936].

⁴Already described and depicted by Al Sufi [964], also described by Marius [1614] and Hodierna [1654], and eventually catalogued by Messier [1774].

⁵To actually prove or disprove LG membership by applying this criterion is rather difficult, because it requires exact 3D velocities and locations relative to the LG barycenter as well as the mass of the potential member which are hard to come by as will be discussed below.

⁶Probably found by Hodierna [1654] and rediscovered by Messier [1774].

⁷First preserved mention by Al Sufi [964]; then again mentioned by Vespucci [1503] and by the survivors of the first circumnavigation of the earth [see the account on Magellan’s voyage of Pigafetta, 1522]. The Large and the Small Cloud began being called *Magellanic* not until the 19th century.

⁸The “dwarf” status of M 32 is still in dispute because it follows the same scaling relations as normal elliptical galaxies [Ziegler and Bender, 1998].

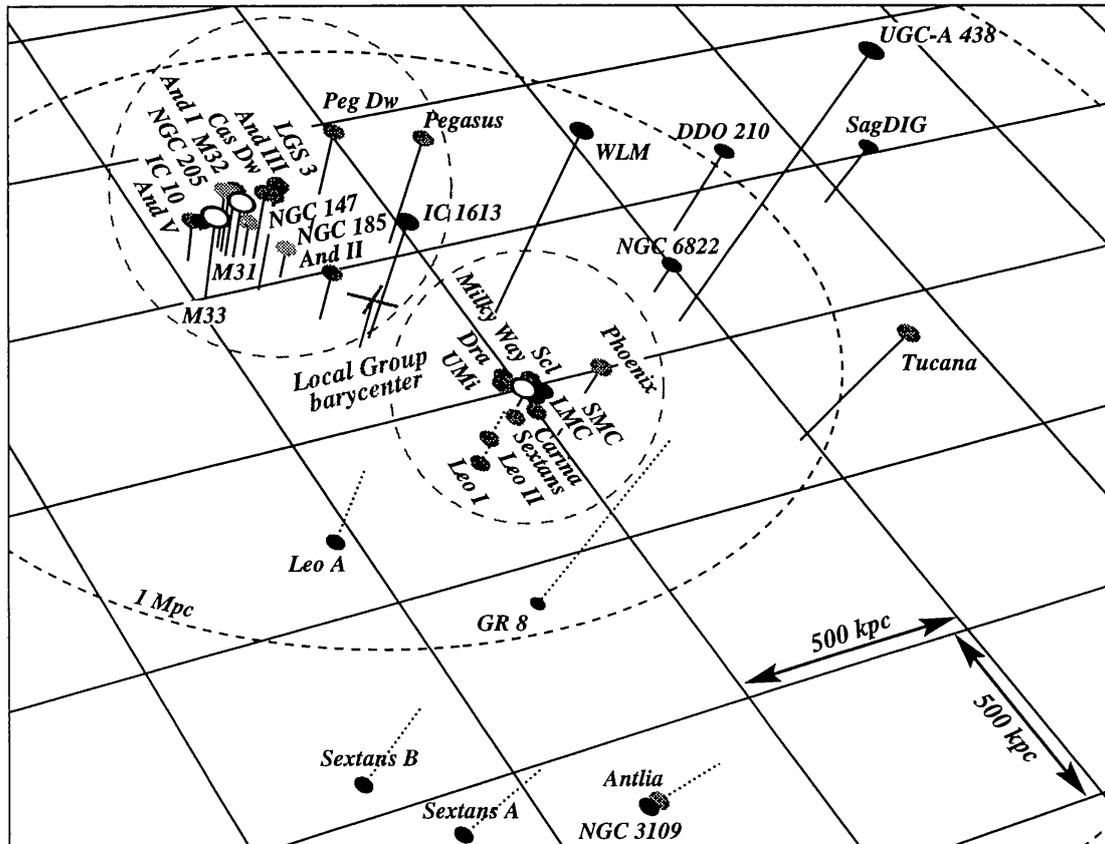

Figure 1.1: Fig. 3 of Grebel [1999]: “A scaled 3-D representation of the Local Group (LG). The dashed ellipsoid marks a radius of 1 Mpc around the LG barycenter (cross). The underlying grid is parallel to the plane of the Milky Way. Galaxies above the plane are indicated by solid lines and below with dotted lines. The dashed circles enclose the presumed M31/M33 and the Milky Way subsystems. Morphological segregation is evident: the dEs and gas deficient dSphs (light symbols) are closely concentrated around the large spirals (open symbols). DSph/dIrr transition types (e.g. Pegasus, LGS 3, Phoenix) tend to be somewhat more distant. Most dIrrs (dark symbols) are isolated and located at larger distances.” Please note that the projection is misleading: Galaxies above the plane appear to be more distant than galaxies below. Not all galaxies of Tab. 1.1 [Mateo, 1998] are shown.

mean metallicity⁹ and enrichment histories, times of their major star formation episodes, fractional distribution of ages and subpopulations. Indeed no two dwarf galaxies are alike, not even if they are of the same morphological type or have similar luminosities.” [Grebel, 2001].

⁹Since “metallicity” is used frequently throughout astrophysical literature and often combined with stellar populations labelled I or II, implicitly referring to metallicity, some explanation shall be given here: Metals in astrophysical terms are all elements heavier than Helium. Stars with about and above solar metallicity as found mostly in the star forming disks of spiral galaxies were called Population I stars whereas stars with well below solar metallicities as found usually in the old MWG globular clusters, its Halo, and in elliptical galaxies were designated Population II stars according to Baade [1944, 1958]. The implicit combination of “recent star forming” with high metallicity is

The LGD type distribution could be interpreted as dIrrs evolving to dSphs near bigger galaxies [Mateo, 1998, Grebel, 2001]. But, because they are more difficult to detect than dIrrs there still may be LG dSphs hiding in the field, and, more important, the proximity to bigger galaxies could also influence the early star formation history of a common dIrr/dSph progenitor [Skillman and Bender, 1995] which would be almost impossible to detect now.

Historically, LG membership was based on the ability to resolve a galaxy into stars (e.g. Baade [1944] or more recently Hoessel et al. [1988]) and to derive a low heliocentric velocity. However, to prove membership at least one reliable distance determination is required. There are two principle distance indicators suitable for the LG: One is to look for absolute features of stellar populations (see Sect. 1.5.1, the HRD), the other utilises period-luminosity relations for variable stars (VS, see Sect. 1.5.3 and 1.5.4). Using intrinsically bright stars helps in observations although bright stars are rare, especially in DGs. Therefore the two main distance indicators for the LG are the TRGB-method (see Sect. 1.5.1¹⁷) and the classical δ Cephei PLR (see Sect. 1.5.4).

1.4 Local Dwarf Irregular Galaxies

What can we learn from dIrrs and their content of variable stars?

- As far-scattered LG galaxies they trace the LG gravity potential and allow to determine the local Hubble flow [e.g. see Karachentsev, 2005, Karachentsev et al., 2006]. To do so accurate distances are crucial which brings us to the next point:
- The LG dIrrs can be used as calibrators to different distance indicators, i.e. different types of VS and HRD features (see next Sect.). The distant dIrrs are small enough to show negligible depth effects, yet close enough to allow deep photometry. While the MWG, M 31, M 33, and also the LMC trace distance relations with metallicities ranging from above solar to about 0.4 solar the dIrrs allow to investigate a metallicity dependence to well below solar values [i.e. 2% solar in Leo A, Skillman et al., 1989]. Since the LMC, which already has sub-solar metallicity [Dufour, 1984], is still the main calibrator for distances beyond the LG and shows distance modulus inconsistency of 0.15 mag in recent publications [Alves, 2004] it is worthwhile to investigate the whole parameter space accessible.
- Compared to large galaxies, especially Spirals, dIrrs are simple systems. Theories about stellar formation histories utilising different types of stars as tracers can be tested more easily with them.

Therefore, we decided to start *VarStarDwarves* as to establish a census of bright variable stars in some LG dIrrs by applying new techniques, i.e. CCD imaging combined with difference imaging photometry suitable for crowded fields.

inadequate for dIrrs which often show recent star formation at very low metallicities. In astrophysics, especially in theory, the composition of stars is usually described in fractions of $X = \text{Hydrogen}$, $Y = \text{Helium}$, and $Z = \text{“Metals”}$. Observing astronomers prefer to give logarithmic ratios of a “test” metal content and hydrogen often normalised to solar values and derived of spectroscopic equivalent widths measurements, e.g. the iron abundance “Fe over H”: $[\text{Fe}/\text{H}] = \log_{10}((\text{Fe}/\text{H})_{*}/(\text{Fe}/\text{H})_{\odot})$.

Table 1.1: A combined selection of Tab. 1 and 2 of Mateo [1998]: “Name, entries in italics refer to the five giant Local Group galaxies that are not discussed in this review in any detail; a common alternative name; right ascension and declination for epoch J2000.0, respectively; galactic longitude and latitude, respectively; galaxy type following van den Bergh [1994]; subgroup membership within the Local Group; true distance modulus and distance.” Also see Fig. 1.1 for “orientation”. This LG census has been the starting point for the VarStarDwarves candidates. The selection process will be detailed in Tab. 2.1, Sect. 2.1.

1.5 “The Variable Star Menagerie”

During its lifetime a star of any mass can become pulsationally unstable at various stages. The classical astronomical classification follows observational quantities which can be derived from broadband photometry in the optical wavebands like absolute brightness, temperature (i.e. colour), period, shape of light curve, and the stellar *vicinity* (e.g. globular cluster, disk of a spiral galaxy etc.). Sometimes a class will be split into subclasses later by concentrating on a previously neglected aspect. A class is often named after the first star found which showed a specific behaviour. The class prototype usually is a nearby star of the galactic solar neighbourhood and might even prove to be not at all physically related with the group labelled by it (e.g. BL Her stars). To complicate things even more the classification boundaries often overlap.

A more physical approach tries to identify the evolutionary phase of a given variable star class or subclass, i.e. its position in the Hertzsprung-Russell-Diagram¹⁰ combined with information on the ranges of masses, ages and metallicities of its members. Following this approach one can learn a lot about the stellar formation history of the *hosts* only by counting the absolute and relative quantities of specific variable stars. The *physical* parameters can be grouped roughly into three mass ranges, two metallicity regimes, and two evolutionary stages, i.e. (close to) main sequence and evolved stars. After a short excursion into stellar evolution following Salaris and Cassisi [2005] and stellar pulsations [Cox, 1974, Gautschy and Saio, 1995, Gautschy, 2003] I will briefly discuss *Period-Luminosity Relations* (PLRs) and summarise the classes of pulsating variable stars which are bright enough to be discovered within the scope of the *VarStarDwarves* project [Ferne, 1969, Madore and Freedman, 1991, Gautschy and Saio, 1996, Becker, 1998, Allen, 2001, Wallerstein, 2002, Sandage and Tammann, 2006].

1.5.1 The Evolution of Single Stars

[Salaris and Cassisi, 2005]

The Main Sequence (MS)

All stars begin their life with Hydrogen core burning on the so called *Zero-Age Main Sequence* (ZAMS, Fig. 1.2) and slowly grow more luminous throughout their main sequence phase. Stars with masses $M_* \gtrsim 1.3 M_\odot$ (upper main sequence, UMS) have a convective core. They first get cooler until their central Hydrogen drops below $X = 0.05$ which because of deficient fusion causes *overall contraction* at consequently raising temperatures¹¹. Again, stars with masses

¹⁰The HRD [Russell, 1913, 1914] plots luminosity vs. temperature of stars. A typical HRD shows a well populated *main sequence* of stars where luminosities increase with temperature corresponding to stars burning hydrogen in their cores. In addition there is usually a vertical sequence of almost constant temperature *evolved* stars which is separated by the *Hertzsprung gap* from the main sequence. (See Fig. 1.2.)

¹¹*Rotational mixing* can prolong the main sequence life time of massive stars and therefore lead to crossing evolutionary tracks when comparing rotating with non-rotating stars [i.e. see Walborn and Lennon, 2004, Fig. 1 and 2]. This would cause ambiguities when estimating ages and masses of stars from their position in the HRD alone not only for the main sequence but consequently also for the evolved phases. However, this theory still lacks observational evidence [Lennon, 2007, priv. comm.].

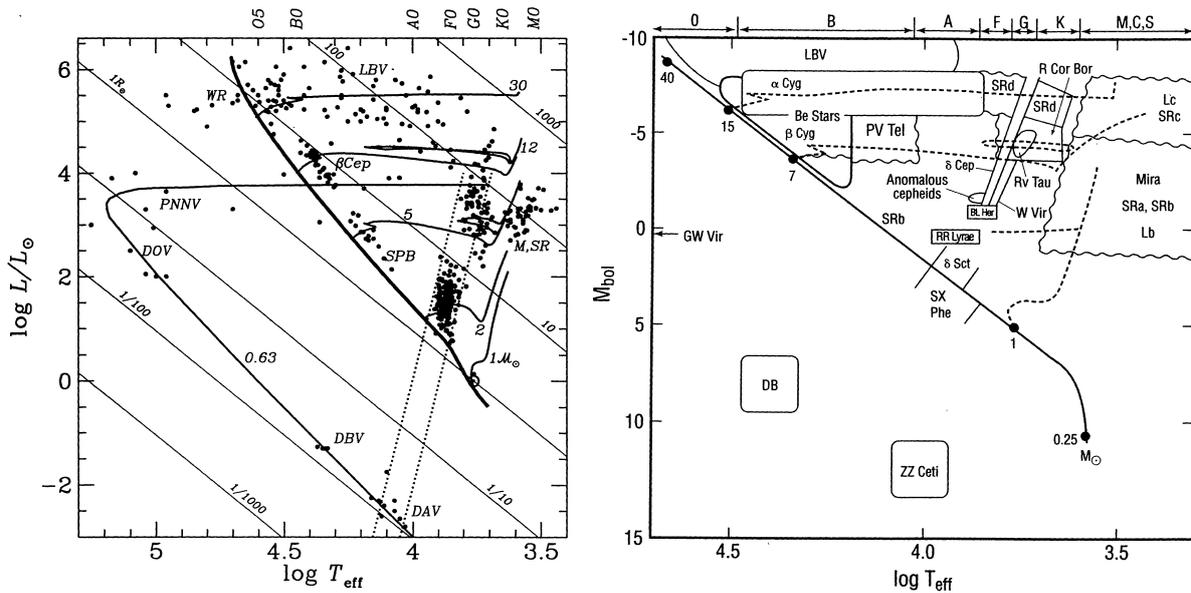

Figure 1.2: Variable Stars in the HRD. Left [Gautschy and Saio, 1995, Fig. 1]: “HR diagram showing the distribution of types of pulsating variables (dots). The heavy line shows the location of the zero-age main sequence for solar abundances. A number of evolutionary tracks, labelled with the masses in solar units, are included. A post-AGB evolutionary path for a $0.63 M_{\odot}$ star is show; it leaves the AGB at constant luminosity and turns later into a white dwarf cooling track. The thin diagonal lines represent loci of constant radius. The classical instability strip and its extrapolation towards the white-dwarf region is indicated by dashed lines. Abbreviations: WR: Wolf-Rayet stars; LBV: luminous blue variables; SPB: slowly pulsating B stars; M: Miras; SR: semiregular variables; PNNV: planetary nebulae nuclei variables; DOV, DBV, DAV: variable DO-, DB-, and DA-type white dwarfs.” Right [Becker, 1998, Fig. 1]: “The approximate position of various types of pulsating variable stars on a M_{bol} vs. $\log T_{\text{eff}}$ H-R diagram. Spectral class boundaries are given at the top of the diagram. The solid curved line represents the Zero-Age Main Sequence corresponding to representative star masses in solar units. The dashed curves are the evolutionary tracks for 1, 7, and 15 M_{\odot} population I models.” (β Cyg should read as β Cep.)

$1.3 M_{\odot} \gtrsim M_* \gtrsim 0.4 M_{\odot}$ (low main sequence, LMS) and radiative cores constantly get hotter. Stars with $M_* \lesssim 0.4 M_{\odot}$ (very low-mass, VLM) are fully convective but too faint on the main sequence and their maximum age¹² is too young for them to have evolved beyond the main sequence. Therefore they are irrelevant for the *VarStarDwarves* project. Lower metallicity shifts the ZAMS to higher temperatures (and luminosities¹³). After $\sim 80 - 90\%$ of their total life time the central Hydrogen is exhausted and the stars start to enter *Post Main Sequence* phases¹⁴.

¹²They live longer than a Hubble time.

¹³But the gain in luminosity does not keep up with the gain in temperature. So a metal poor ZAMS appears to be shifted to the left in the HRD when compared to a solar metallicity one.

¹⁴The corresponding position in the HRD is the so called *turn-off point* (TO) of a star. The HRD of stars of a range of masses but with identical ages shows a main sequence which stops at an age corresponding to a mass reflecting

The Sub-Giant and the Red Giant Branch (SGB & RGB)

After Hydrogen burning has ceased in the centre of a star it still continues in a shell around the Helium core. *Low mass stars* ($\lesssim 2.3 M_{\odot}$) have a fractional Helium core below the *Schönberg-Chandrasekhar limit* [Schönberg and Chandrasekhar, 1942] which provides enough pressure to support the overlying envelope. More massive stars have a slowly contracting core until the onset of Helium burning. All stars go through the Sub-Giant phase (SGB) with an expanding, successively cooler envelope at almost constant luminosity¹⁵. For more massive stars this phase is increasingly shorter resulting in the *Hertzsprung gap* in the HRD. In the subsequent Red Giant phase (RGB) the stars get more luminous at almost constant temperature climbing up a track in parallel to, but “bluer” than, the *Hayashi track*¹⁶. The RG phase ends for the low mass stars at the Tip of the Red Giant Branch¹⁷ (TRGB) with a series of Helium flashes¹⁸, which finally reach the core, and a drastic drop in luminosity during this short (1 Myr) transition phase. The more massive stars start Helium core burning in a non-degenerate state without any Helium flashes and at a successively younger phase. For very high mass stars the RG phase can completely disappear. (See evolutionary tracks in Fig. 1.2.)

The Helium Core Burning Phase

The Helium core burning phase is the second longest in the life time of a star¹⁹. The evolutionary paths stars take are determined now by their Helium core mass, their total mass, as well as the abundance of Helium and metallicity in their envelope. These paths can get very complicated when taking into account mixing processes like *convective overshoot*, *induced semi-convection* or *breathing pulses* which are beyond the scope of this simplified review. (Again, see tracks for different masses in Fig. 1.2.)

The Horizontal Branch (HB): When their Helium flashes finally have completely removed degeneracy from the core low mass stars settle on the *Zero-Age Horizontal Branch* (ZAHB) a more or less horizontal stripe in the HRD. Increasing envelope masses follow a decreasing temperature. The actual position and morphology of the HB depends mostly on Helium abundance and metallicity of the envelope. Roughly speaking, increasing metallicity (Z) successively depopulates the blue part of the HB while with increasing Helium abundance (Y) the HB grows

the successive shorter main sequence life time with growing mass and therefore increasingly efficient Hydrogen core burning. All stars of that age brighter than the turn-off point will have evolved to lower temperatures.

¹⁵The physical reasons why stars become Red Giants are still unclear [e.g. see Chiosi, 1998, Sect. 2.2, last paragraph and references therein]!

¹⁶Hayashi [1961] described the evolutionary track of the fully convective phase of *Pre-Main Sequence* stars. Those protostars have reached hydrostatic equilibrium and contract on the Kelvin-Helmholtz timescale [Thomson (Lord Kelvin), 1862, Helmholtz, 1871] with dropping luminosity at almost constant temperature.

¹⁷The TRGB luminosity is for stars below $1.8 M_{\odot}$ almost independent of mass/age and only slightly dependent of metallicity and therefore a good indicator for extragalactic distances [Lee et al., 1993].

¹⁸I.e. phases of unstable nuclear Helium burning because of a thermal runaway processes.

¹⁹Unless one considers *stellar corpses*, like white dwarfs and neutron stars, as stars still being alive. They, off course, easily outlast the corresponding preceding main sequence phase.

more luminous. The position and extension of the HB therefore is mostly a indicator for the chemical composition of a stellar population.

Blue Loops: Intermediate mass stars perform a *blue loop* in the HRD: Starting from the RGB they first drop in luminosity at almost constant temperature like “retreading” on the RGB²⁰. Then they grow again in luminosity but now also in temperature, the ratio depending on mass but also on metallicity, following the increasing energy release of the Hydrogen burning shell which delivers about 80% of the nuclear burning energy at the bluest point of the loop. Subsequently the stars still grow more luminous but start to cool down again to the point where Helium burning contributes about one third of the total energy budget. The loop is closed by a drop in temperature in parallel to its first rise on the loop until the star reaches a point near its starting point on the RGB now with a $\approx 60\%$ energy contribution of Helium core burning. Depending on the chemical composition and the presence of mixing processes mentioned above secondary loops on this path can occur.

Blue Supergiants: Massive stars above $8 - 10 M_{\odot}$ ignite Helium in their core before they reach the RGB configuration and are still on their monotonic way to the red on the HRD when they exhaust their core Helium and almost immediately start to ignite carbon in non-degenerate conditions.

The Asymptotic Giant Branch (AGB)

As the Helium in the core gets consumed the stars enter the *Asymptotic Giant Branch* with a first phase of Helium shell burning which closely resembles the RGB phase²¹. Throughout this phase all stars drop in effective temperature and grow in luminosity, again almost in parallel to the Hayashi track¹⁶. At the onset of Helium shell burning the overlying Hydrogen burning shell extinguishes²². Massive stars²³ will eventually ignite their carbon core while low and intermediate mass stars enter the *thermally pulsating AGB phase* (TPAGB). The TPAGB starts when the Helium shell burning dies down because it reaches the Hydrogen/Helium discontinuity with a reignition of the Hydrogen shell. The Helium ashes of the burning Hydrogen shell accrete above the degenerate CO core. When those ashes exceed a critical mass²⁴ a thermonuclear runaway (thermal flash) expands the Hydrogen shell and thereby throttles its burning. As the runaway dies down quiescent Helium burning commences and lasts until the Helium ashes are spent.

²⁰At least if they have reached the RGB before they start Helium core burning which strongly depends not only on mass but also on metallicity. If they are still on the SGB they begin the blue loop right where they are thereby only performing only a partial loop.

²¹For low mass stars the resemblance in the effective temperature-luminosity relation is very close, just slightly hotter, i.e. it follows *asymptotically* the RGB.

²²For stars above $3 - 5 M_{\odot}$ immediately.

²³The M^{up} limit is given by the largest mass with enough electron degeneracy of the CO core to prevent carbon ignition and depends strongly on the initial chemical composition. It is $\approx 8 M_{\odot}$ for solar and extremely low metallicity and minimal with $\approx 4 M_{\odot}$ for $Z \approx 0.001$ stars.

²⁴I.e. $10^{-3} M_{\odot}$ for a $0.8 M_{\odot}$ CO core.

Now the hydrogen shell reignites and the cycle starts over while the star continues to climb up the AGB. Frequent cycles will occur during which high mass loss due to stellar winds and large amplitude pulsations (*Mirae*⁴⁹) prevent even intermediate mass stars to grow a CO core beyond the *Chandrasekhar mass limit* ($\approx 1.4 M_{\odot}$) which would ignite carbon. The (TP)AGB lasts about several 10^6 years.

Final stages

Massive stars will go through a short series of successive burning of Carbon (10^3 years), Neon (years), Oxygen (years), and Silicon (days) before they finally explode as *Type II supernovae*. Lower mass stars will finally leave the tip of their AGB path rapidly getting hotter at constant luminosity as they evolve to the *white dwarf* (WD) phase²⁵.

1.5.2 Pulsational Instability – The κ -mechanism

Shapley [1914] and Plummer [1914] were the first to argue in favour of a pulsation mechanism in single stars to overcome the growing difficulties of explaining observational properties of some variable stars with a pure “binary picture”²⁶. Already Ritter [1879]²⁷ had shown a radially and adiabatically pulsating homogeneous sphere follows

$$P \propto \sqrt{R/g} \propto \sqrt{R^3/M} \Rightarrow P \sqrt{\rho} = Q \quad , \text{ with}$$

P = period,	R = radius,
g = surface gravity $\propto M/R^2$,	M = mass of the sphere
ρ = mean density, and	Q = the resulting pulsational constant.

But it was Eddington [1918, 1919, 1926] who developed the basic theory of stellar pulsation. In principle any star can experience radial pulsations, however, it needs an excitation mechanism to continuously drive the pulsation, otherwise it will be damped within short time scales²⁸. The most prominent under those excitation mechanisms is the κ -mechanism²⁹ which is probably the source for all classes of radially pulsating stars. It can occur in any layer of a star where the opacity κ drops with temperature which again is the case within ionisation layers. The most

²⁵While some stars immediately enter the WD cooling sequence, others “say farewell” with a *self-induced nova*, and some can even recover one last time as a so called *born-again AGB*.

²⁶While there still were publications defending the binary hypothesis for Cepheids (see next Sect.) until 1943 Baade [1926] could prove the pulsation premise with a test which was several times improved up to Wesselink [1946]. This method now is known as Baade-Wesselink method for a physical calibration of classical pulsators.

²⁷Ritter’s work was reviewed by Emden [1907] in his famous “*Gaskugeln*” otherwise, however, completely ignored by the astronomical community.

²⁸A few thousand years.

²⁹While Eddington already described this *valve-mechanism* he still rejected it as source for stellar pulsations [Eddington, 1941].

important layer³⁰ is the boundary of He^+ to He^{2+} , nevertheless, it is not the only one³¹. The drop in opacity is due to a decreasing number of free electrons which provide Thomson scattering. The cycle works like follows:

- We start with compressing a stellar atmosphere layer where opacity grows with temperature, i.e. this layer moves inwards. This compression raises the temperature of the layer and therefore also its opacity.
- The increased opacity leads to retained radiation below, i.e. the radiative pressure in the adjacent lower layer increases which, again, drives the layer towards expansion.
- The expanding layer cools decreasing the opacity. Now, the retained radiation can escape quickly
- The radiative pressure below the layer drops. It will again be compressed moving inwards and the cycle starts over.

The working of a κ -mechanism is confined to special regions in the HRD, the instability strips³². At present the theory of pulsating stars has matured even beyond semi-analytical non-adiabatic models. It can reproduce the position and extent of the instability regions of many of the variable stars classes depending on physical input parameters. To give only a short summary on latest work in the field would already go beyond the scope of this introduction. Therefore, I will only give a few recent references relating to the variable stars of Sect. 1.5.4: Marconi et al. [2005] on “*Cepheid Pulsation Models at Varying Metallicity and $\Delta Y/\Delta Z$* ”, Marconi and di Criscienzo [2007] on “*Updated pulsation models for BL Herculis stars*”, Fiorentino et al. [2006] on “*Synthetic properties of bright metal-poor variables. I. “Anomalous” Cepheids*”, and Miglio et al. [2007] on “*Instability strips of slowly pulsating B stars and β Cephei stars [...]*”; W Virginis and RV Tauri stars lack very recent publications, the latest were Bono et al. [1997] on “*Evolutionary scenario for metal-poor pulsating stars. I. Type II Cepheids.*” and Fokin [2001] on “*RV Tauri stars*” in “*Stellar pulsation - Nonlinear Studies*”. However, theory is still far from completed: “*We must remember that we do not understand the mechanisms shaping the light curve.*” [Gautschy and Saio, 1996, and still true] to name only one example.

1.5.3 Period-Luminosity Relations

In 1908 Leavitt [1908] discovered the first *Period-Luminosity Relation* (PLR) based on 16 variable stars³³ out of a total of 1777 in the Magellanic Clouds. Successively, in Leavitt and Pickering [1912], she found that the brightness at maximum and at minimum of 25 variable stars in

³⁰The He^+ ionisation layer as the main origin for the Cepheid pulsations was uncovered by Zhevakin [see 1963, for a extensive list of his references] and Cox and Whitney [1958]. They fought a sort of *Cold Star Wars* over that topic.

³¹E.g. the instability region of β Cephei and SPB stars (see below, Sect. 1.5.4) is due to the *iron opacity bump* [Kiriakidis et al., 1992, Moskalik and Dziembowski, 1992].

³²The *classical instability strip* for Cepheids has been introduced by Sandage [1958].

³³With a sufficient number of observed epochs.

the Small Magellanic Cloud follows closely a linear relation with the logarithm of their periods. Hertzsprung [1914] was the first to establish a PLR which can be translated to the modern form

$$\langle M \rangle = a \log_{10} P + b, \quad \text{with} \quad (1.1)$$

M = mean absolute brightness³⁴ and P = period, using Leavitt's data to determine the slope a and statistical parallaxes³⁵ of 13 galactic Cepheids for the zero point (ZP) b ³⁶. Shapley [1918] repeated the work of Hertzsprung but included Globular Cluster (GC) Cepheids which should prove to be fatal: The determination of the PLR ZP was greatly hampered by ignoring interstellar absorption³⁷ (nowadays often called *reddening*). In addition, effects of galactic rotation were unknown at that time. Together with further systematic errors of the proper motions the zero point derived from local Population I Cepheids³⁸ was too dim by 1.5 mag. Now, Population II Cepheids³⁸ are intrinsically fainter by 1.5 visual magnitudes and, being GC members off the galactic plane, suffer only from little interstellar absorption. Therefore later distance determinations to GCs by the use of RR Lyrae stars³⁹ were in perfect agreement with Cepheid PLR distance moduli [e.g. see Bok and Boyd, 1933]. Thus, the inclusion of GC Cepheids was able to obscure the wrong ZP for almost 40 years until Baade [1954, 1956] actually *rescaled* the universe by almost a factor of two at a meeting during the 1952 IAU meetings in Rome⁴⁰. The astronomical community, having successfully supported Shapley's ZP until then, now leaped at confirming and refining the new ZP⁴¹. During the next decades observations and theory tried to converge and to actually link empirical period-luminosity-colour relations (PLCRs) with theoretical predictions about the width of the instability strip as well as the dependence of both the ZP and the slope of the PLCR of Classical Cepheids³⁸. But the correction for interstellar absorption proved to be very difficult until the advent of modern multi-wavelength photometry including near infrared bands⁴². At the time of the start of the Hubble Space Telescope (HST) key project on the

³⁴In particular M_V , the absolute V -band (visual band) brightness.

³⁵I.e. mean secular parallaxes.

³⁶Hertzsprung [1914] in modern form would translate to $\langle M_V \rangle = -0.6 - 2.1 \log P$, which is, mostly because of the big errors of the statistical parallaxes, more than a magnitude brighter than recent PLR determinations. Additionally, a presumably typographical error translated his derived SMC parallax of 0.0001 only to 3000 ly and not 30000 ly.

³⁷The existence of interstellar absorption in the galactic plane was not established beyond doubt until Trumpler [1930].

³⁸See next Sect.

³⁹They populate the cross section of the classical instability strip and the horizontal branch (HB).

⁴⁰Essentially he reported that the new 200-inch Mt. Palomar telescope did not reveal any RR Lyrae stars³⁹ in M 31 which it should have done if Hubble's Cepheid PLR distance to M 31 was correct. Hubble [1925] had settled the *Great Debate* with the discovery of Cepheids in some of the controversial *nebulae*, i.e. M 31 and M 33, and applying a PLR.

⁴¹Fernie [1969]: “*The definitive study of the herd instincts of astronomers has yet to be written, but there are times when we resemble nothing so much as a herd of antelope, heads down in tight formation, thundering with firm determination in a particular direction across the plain. At a given signal from the leader we whirl about, and, with equally firm determination, thunder off in a quite different direction, still in tight parallel formation.*”

⁴²Madore and Freedman [1991]: “*Before we can approach an empirical determination of the coefficients in the PLC relation (or any determination of their variation with metallicity) we must solve the reddening problem. While theory predicts a finite width to the instability strip (with temperature/color being the controlling parameter), and while metallicity is a quantity that is known to be different from galaxy to galaxy (and it is known to vary*

extragalactic distance scale (1990) using PLRs as a measure of the local extragalactic distance scale finally seemed to be firm ground. While theory and observations still struggled to solve the impact of metallicity and Helium abundances one was nevertheless tempted to cite Hubble [1936, on Shapley’s PLR]: “*Further revision is expected to be of minor importance.*”, meaning only in the order of 0.1 mag. But, again, there now exists profound evidence that the PLRs of the MWG and the LMC differ in slope and ZP at the 0.3 mag level⁴³. While those discoveries will ultimately help to lift PLR distances to a new level of accuracy, for now, present day PLR distances should not be taken absolutely but only relative to their calibrator. The study of other PLRs than that of Classical Cepheids has been neglected since Baade [1954] until recent³⁸.

Historically PLRs were and still are calibrated in the visual optical *V*-band⁴⁴. The addition of *colour* information to derive reddening and temperature first involved the blue *B*-band⁴⁵ and later on mostly the optical infrared *I*-band⁴⁶. For *VarStarDwarves* the use of the *V*-band was out of the question⁴⁷ as it is not suitable to achieve a high signal-to-noise (*S/N*) ratio with the instruments and observation sites at hand. Also our interest in red, long-period variables (LPV) led us to invest most of the observations into the red *R*-band⁴⁸. When applying PLRs to our data we were therefore restricted to the rare publications of *R*-band PLRs, but, as will be detailed in the next section, those proved to be adequate for the aim of our survey. To account for the different PLRs for fundamental mode (FM) and first overtone (FO) pulsators we follow Caputo et al. [2004]:

$$\log P_{\text{FM}} = \log P_{\text{FO}} + 0.13 \quad (1.2)$$

More information and literature about recent work on PLRs is detailed in the next Sect. according to the VS types relevant for *VarStarDwarves*.

1.5.4 Bright “Blue” Pulsating Variable Stars

The Mirae⁴⁹ stars, i.e. red, long-period variables on the TPAGB in the HRD, within our sample have been already discussed in detail in Snigula [2006] and therefore will be ignored here completely. (The position of subsequent VS types in the HRD is displayed in Fig. 1.2.)

systematically within individual galaxies), only when reddening has been accounted for can we go on to look for meaningful correlations of luminosity residuals with intrinsic color and/or metallicity, for instance.” In Freedman and Madore [1990] they were convinced to have shown that the impact of metallicity has to be less than 0.13 mag.

⁴³See Sandage and Tammann [2006] and references therein.

⁴⁵Centred on 450 nm for the *B – V* colour.

⁴⁶Centred on 850 nm for the *V – I* colour.

⁴⁷See Sect. 2.4 and 3.1.1 on the choice of filters.

⁴⁸Centred on 650 nm.

⁴⁹*o*Ceti was the first variable star to be found pulsating later. It was originally discovered by Fabricius [1596], got its first period assessment by Holwarda [1640] and its **miraculous** name by Hevelius [1662]. (Find further details on the history of Mira in Hoffleit [1997].)

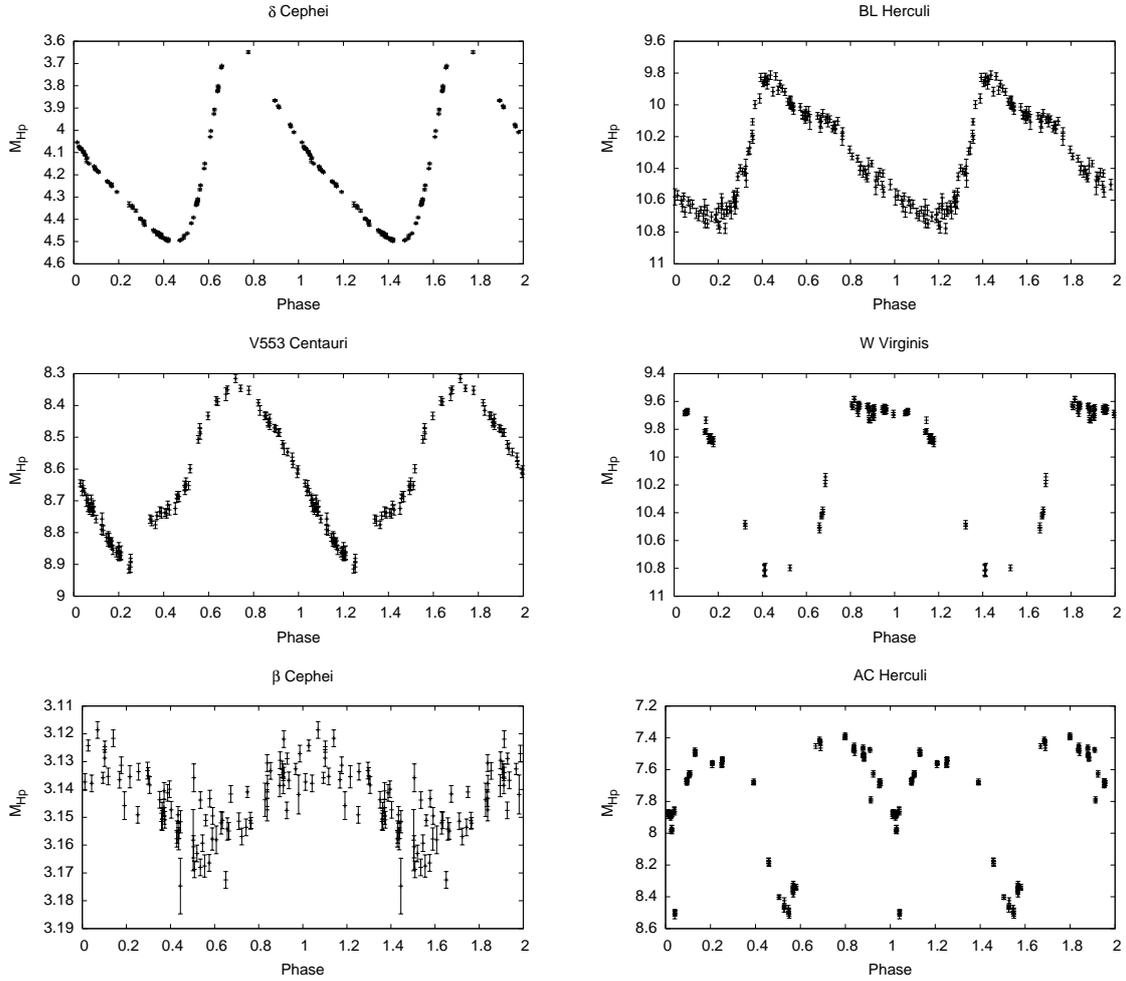

Figure 1.3: Hipparcos [ESA, 1997] photometry light curves of prototype pulsating variable stars.

Classical δ Cephei Stars (CCs)

Goodricke [1786] was the first to report on “*A Series of Observations on, and a Discovery of, the Period of the Variation of the Light of the Star Marked δ by Bayer*⁵⁰, *Near the Head of Cepheus*” which became the prototype of both, all Cepheid variables and the δ Cephei subclass, arguably the most prominent type of all variable stars⁵¹. Classical δ Cephei stars are intermediate mass, Helium core burning stars crossing the *classical* instability strip of the HRD on their blue loop⁵² (see Sect. 1.5.1 and 1.5.2). They have periods from 1 to 130 days, amplitudes from 0.1 to 2

⁵⁰Bayer [1603].

⁵¹Actually, the first δ Cephei type variable star was discovered a month before Goodricke discovered δ Cephei by his friend and neighbour Pigott [1785]: η Aquilae, i.e. at that time still η Antinoi.

⁵²See Hofmeister et al. [1964], Lauterborn et al. [1971]. Probably they need masses $M_* > 5M_\odot$ to have the blue loop extending into or crossing the instability strip. But then they might cross the strip even several times.

magnitudes and follow a well defined PLR [Becker, 1998]. Their light curves (Fig. 1.3, top, left) have a steep rise followed by a shallow decline with the exception⁵³ of the short-period s-Cepheids⁵⁴. From $4 \text{ d} < P < 20 \text{ d}$ there exists a *bump* in the light curve which shift of location with period is known as *Hertzsprung progression*⁵⁵. The most recent PLR calibration in the *R*-band is that of Madore and Freedman [1991] which also served as the reference for the HST key project on the extragalactic distance scale⁵⁶:

$$M_R = -3.04(\pm 0.17) \cdot (\log P - 1.00) - 4.48(\pm 0.08) \quad [\pm 0.25] \quad (1.3)$$

The photometric precision of *VarStarDwarves* is at about the same level of accuracy as the relation.

Population II Cepheids

The post-main-sequence Population II Cepheids consist of three distinct groups:

BL Herculi stars should actually better be labelled **XX Virginis** after their true metal poor prototype or *above horizontal branch 1* (**AHB1**) stars [Diethelm, 1990]. BL Herculi itself (Fig. 1.3, top, right) is the Population I, metal rich equivalent, but belongs to the same group in terms of evolutionary status. AHB1 stars originate from blue HB stars crossing the instability strip as they evolve towards the AGB⁵⁷. Whatever they are called, they have periods of about 1 to 5 days and amplitudes up to 1.5 mag.

There is a paucity of Type II Cepheids with periods of 5 to 10 days, which is presumably due to the different evolutionary status of the two groups, XX and W Virginis [Gautschy and Saio, 1996].

W Virginis stars are either AGB on a blueward excursion during late Helium shell flashes or already on their final departure from the AGB. Besides being fainter their light curves resemble those of classical δ Cephei stars (Fig. 1.3, centre, right). They have periods of 10 to 35 days and 0.3 to 1.2 mag amplitudes.

⁵³“**EXCEPTION**, n. A thing which takes the liberty to differ from other things of its class, as an honest man, a truthful woman, etc. ‘The exception proves the rule’ is an expression constantly upon the lips of the ignorant, who parrot it from one another with never a thought of its absurdity. In the Latin, ‘*Exceptio probat regulam*’ means that the exception *tests* the rule, puts it to the proof, not *confirms* it. The malefactor who drew the meaning from this excellent dictum and substituted a contrary one of his own exerted an evil power which appears to be immortal.” [Bierce, 1906]

⁵⁴With periods of $P \lesssim 7 \text{ d}$ and low amplitude sinusoidal light curves.

⁵⁵This bump is due to an accidental 2:1 ratio of the fundamental mode and the second overtone mode periods [Simon and Schmidt, 1976].

⁵⁶Despite the doubts of the uniformity of the classical Cepheid PLR [Sandage and Tammann, 2006] Rizzi et al. [2007] found the Madore and Freedman [1991] PLRs consistent at the 1% level in average and 0.1 mag per case with distance determinations they have derived for 16 galaxies with the TRGB-method, which they believe to be correct to at least 0.1 mag.

⁵⁷According to theory AHB1 stars should have slowly increasing periods [Sandage et al., 1994] which has been actually observed [Diethelm, 1996].

RV Tauri stars are most probably AGB stars right at the end of their life getting hotter and crossing the instability strip while they leave the AGB [Jura, 1986]. They show group-defining double-wave light curves whose origin is still controversial (Fig. 1.3, bottom, right, AC Herculi). Their *formal* period is about 30 to 150 days and they have amplitudes up to 5 mag.

Type II PLRs are not only fainter than their Population I analogue but, according to Sandage and Tammann [2006], also show a different slope⁵⁸. Alcock et al. [1998] selected 30 W Virginis and RV Tauri stars from their MACHO-LMC data base. They are the only ones to give not only a V-band PLR but also a PLCR based on V and R-band data. From their R-band data alone I derived

$$M_R = -3.05(\pm 0.29) \cdot (\log P - 1.00) - 2.07(\pm 0.10) \quad [\pm 0.39] \quad . \quad (1.4)$$

Selecting only stars with $V - R < 0.325$, i.e. the bluest and therefore probably least affected by extinction ones, yields

$$M_R = -3.04(\pm 0.25) \cdot (\log P - 1.00) - 2.41(\pm 0.11) \quad [\pm 0.36] \quad . \quad (1.5)$$

(See Fig. 1.4.) Their data indicates a brightening of the PLR at longer periods, i.e. an increasingly steeper slope of the PLR for the longer period RV Tauri. One has to emphasise that different V-band PLRs of Type II Cepheids derived so far from theory, Galactic Globular Clusters, and the LMC are barely consistent within their rather huge errors. [See Alcock et al., 1998, , their Tab. 3 and references therein]. Nevertheless, a single PLR for all types of Population II Cepheids is still adequate until better calibrations are available.

Anomalous Cepheids (ACs)

Anomalous Cepheids are short period, low metallicity pulsators, but too bright (and massive) for ordinary XX Virginis stars, although still too low mass for CCs. The last reviews about Cepheids [Gautschy and Saio, 1995, Wallerstein, 2002, Sandage and Tammann, 2006] still assume that they manage to reach their position in the HRD by mass transfer in a binary system. However, Caputo et al. [2004] offers an alternative explanation which would also solve the *AC mystery*, i.e. why ACs are only found in very metal poor Dwarf Spheroidals (and some Dwarf Irregulars) but not in comparably metal poor Galactic Globular Clusters: Referring to Caputo and degl'Innocenti [1995], Castellani and degl'Innocenti [1995] they explain that at low metallicity the ZAHB stops to get cooler with growing mass but starts to get hotter again, leading to a *ZAHB turn-over* and an *upper HB* which intersects the instability strip again. As a group, ACs have periods of 0.8 to 2 days and amplitudes up to 2 mag. Their light curves are more symmetrical than that of both, CCs and Type II Cepheids (Fig. 1.3, centre, left, V553 Centauri). Recent V-band PLR determinations [Pritzl et al., 2002, Gallart et al., 2004] indicate that AC PLRs are easily consistent with Madore and Freedman [1991] CC PLRs within the scope of *VarStarDwarves*. In contradiction to theory [Caputo et al., 2004] Pritzl et al. [2002] and Gallart et al. [2004] derive slightly different slopes

⁵⁸This statement strongly depends on the selected calibration. Madore and Freedman [1991] and Alcock et al. [1998] PLRs show almost identical slopes!

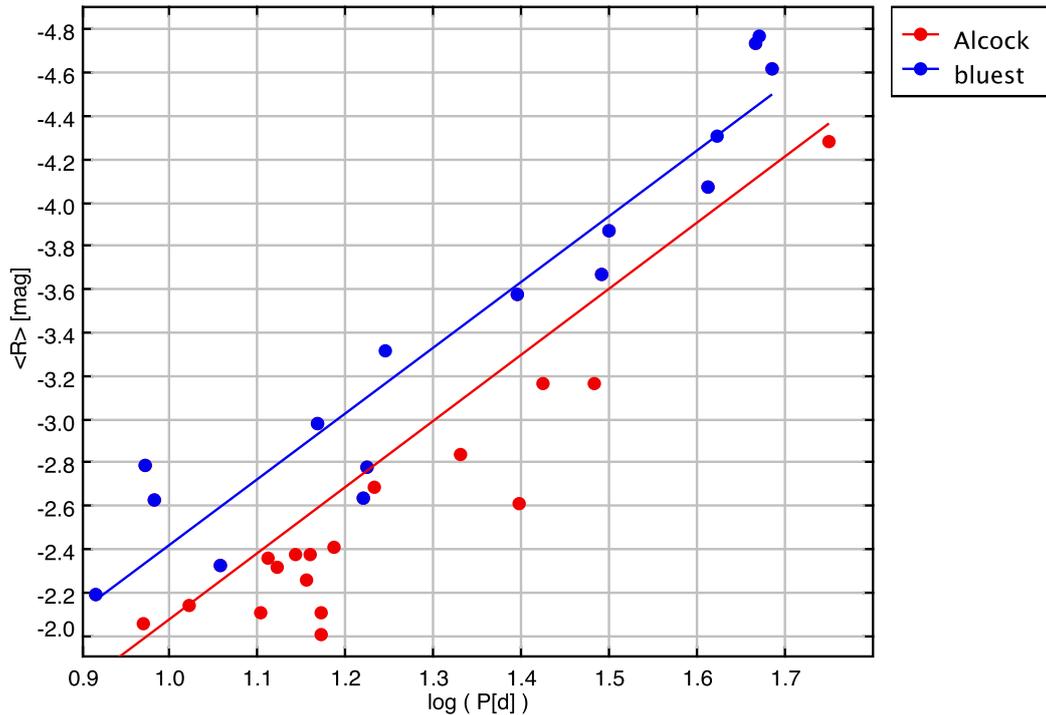

Figure 1.4: Type II Cepheid R -band PLR fitted to the data of Alcock et al. [1998] with a LMC distance modulus of $m - M = 18.5$ (Eqn. 1.4). Red & blue: The stars selected by Alcock et al. [1998] for their PLCR; blue: Stars with $V - R < 0.325$.

for their fundamental mode and first overtone mode pulsators. Because there are no R -band overtone modes PLRs published at all I will use Eqn. 1.2 nevertheless.

β Cephei and Slowly Pulsating B (SPB) Stars

β Cephei and SPB (or 53 Persei) stars are both main sequence pulsating B-stars (Fig. 1.3, bottom, left). The probability of a B-star falling into the according instability region in the HRD is a function of age and metallicity. Only late B-stars with a sufficient metallicity can become a β Cephei star. They have periods of hours and amplitudes of 0.1 mag. For SPBs either a younger age or an inferior metallicity will suffice. They have periods of about 10 h to several days. Since the *VarStarDwarves* galaxies are all in the low metallicity regime we would not expect to actually find any of those variables⁵⁹, but, since they would be detectable in terms of periods, amplitudes, and magnitudes we checked our data without prejudices.

⁵⁹There were no β Cephei stars at all known in the metal poor LMC until Pigulski and Kołaczowski [2002] who found finally 3 out of 27663 B-stars.

Other “blue” Variables

All stars with bolometric magnitudes $M \lesssim -1$ are definitely too faint to be discovered with our survey (see Sect. 4.6.3 and App. D). So RR Lyrae stars³⁹, the Population I and II Dwarf Cepheids⁶⁰, and the pulsating white dwarfs can be neglected here, also.

Non-periodic or eruptive Variables, like all types of *Luminous Blue Variables*⁶¹ (LBVs) or Novae, are too rare to have the chance of appropriate sampling during relevant phases within the *VarStarDwarves* schedule (Sect. 2.5) and therefore have also been excluded from further studies for the time being.

1.5.5 Eclipsing Binaries

While the *VarStarDwarves* data almost certainly contain eclipsing binaries we did not explicitly look for them up to now. In order to derive the binary system parameters which would ultimately yield means of a distance determination to the system one needs high precision spectroscopy in addition to highly accurate photometric data. The DIRECT project [Bonanos et al., 2006] has recently determined a distance modulus to M 33 utilising a detached eclipsing binary⁶² (DEB). A DEB bright enough for spectroscopy in the Local Group neighbours⁶³ will have to be a pair of main sequence, bright B-, if not O-stars. The chances to find such a pair in our sample of DGs are almost zero. Much more promising is the search for semi-detached systems⁶⁴ which not only should be much more frequently bright enough but also would provide additional constraints on the system parameters in their light curves, e.g. photometric mass ratios [Kopal, 1959, pp. 490-496]. All suitable candidates will be contained within the Lomb [1976] selected sample of Tab. 4.4 (last column).

⁶⁰ δ Scuti (or AI Velorum) and SX Phe stars: Stars of spectral classes A-F on the main sequence.

⁶¹Conti [1984], i.e. P Cygni stars, S Doradus stars, and Hubble-Sandage variables.

⁶²See Kuiper [1941], Kopal [1955] for a physically meaningful classification of eclipsing binaries.

⁶³Even with a modern 10 m class telescope.

⁶⁴They are also called *Algol* type systems after their prototype β Persei. The variation of Algol (Arabic for “malignant spirit”) is most probably known since ancient times and the cause for its ill reputation in astrology. (There are hints of Algol’s variation, i.e. related to “Gorgon’s eye”, even back in Homer’s *Illiad*.) Montanari [1671] systematically observed the variation of Algol between 1668 and 1677 which was another blow to the dogmatic view of the Christian church that the universe was immutable. Goodricke [1784] was the first to interpret the variation as a stellar eclipse.

Chapter 2

Observations

2.1 Candidate Selection

2.1.1 Preselection

Using the compilation of Mateo [1998] we selected the dwarf galaxy candidates to be examined with test observations (Tab. 2.1). The evaluation criteria taken into account were: apparent scale and brightness of the object must be compatible with the instrumentation available, visibility from our observation site, and existence of a young star population to increase the probability of finding δ Cephei stars.

The candidates can be grouped according to their right ascension.

- Pegasus, WLM, IC 10, LGS 3, IC 1613
- EGB 0427+63
- Leo A, Sextans B, Sextans A
- GR 8
- NGC 6822, Aquarius

In order to achieve good sampling the “collision” of best visibilities for the objects should be avoided with the final candidates. Fortunately the candidates accumulate at “winter” right ascensions, were nights at Mt. Wendelstein are significantly longer.

2.1.2 Final Selection

The final selection was done mainly considering the results of the test observations. Furthermore a sufficient distance in right ascension between the individual galaxies and the lack of an already published exhaustive search for variable stars in the objects were mandatory. Finally we had to choose objects which would not interfere too much with the WeCAPP pixellensing project also conducted at Wendelstein observatory [Riffeser et al., 2001, Riffeser, 2006]. So we decided to go for Pegasus, EGB 0427+63, Leo A, GR 8, Aquarius, and, if possible, LGS 3 which does interfere with WeCAPP, but is the only object in this sample doing so.

Table 2.1: Known properties of the dwarf galaxy candidates for test observations at the time of selection. [Mateo, 1998]

WLM -15δ , 00 h 01 m RA

pros: strong young stellar population, long night; cons: low declination; additional information: already 15 Cepheids discovered, average distance (within local group).

IC 10 $+59\delta$, 00 h 20 m RA

pros: high declination, long night, only 5-9 Cepheids discovered; cons: low galactic latitude, many foreground stars; additional information: average distance.

LGS 3 (Pisces Dwarf) $+22\delta$, 01 h 03 m RA

pros: long night, no Cepheids discovered; cons: weak young stellar population; additional information: average declination and distance.

IC 1613 $+02\delta$, 01 h 04 m RA

pros: strong young stellar population; cons: low declination, already 77 Cepheids discovered; additional information: average distance

EGB 0427+63 (UGCA 092) $+63\delta$, 04 h 32 m RA

pros: high declination, very long night, no Cepheids discovered; cons: low galactic latitude, many foreground stars, high galactic extinction; additional information: unknown distance.

Leo A (DDO 069, Leo III) $+30\delta$, 09 h 59 m RA

pros: long night, high declination, strong young stellar population, only 5 Cepheids discovered; additional information: average distance.

Sextans B $+5\delta$, 10 h 00 m RA

pros: long night, strong young stellar population, only 7 Cepheids discovered; cons: low declination, long distance.

Sextans A -4δ , 10 h 11 m RA

pros: long night, very strong young stellar population, only 10 Cepheids discovered; cons: very low declination, long distance.

GR 8 (DDO 155) $+14\delta$, 12 h 58 m RA

pros: strong young stellar population, only 1 Cepheid discovered; cons: long distance; additional information: average length of night, almost average declination.

NGC 6822 -14δ , 19 h 44 m RA

pros: very strong young stellar population, short distance; cons: very low declination; additional information: 13 Cepheids already discovered.

Aquarius Dwarf (DDO 210) -12δ , 20 h 46 m RA

pros: strong young stellar population, no Cepheids confirmed; cons: very low declination; additional information: average distance.

Pegasus Dwarf Irregular (DDO 216) $+14\delta$, 23 h 38 m RA

pros: strong young population, only 7-10 Cepheids discovered; additional information: average distance, almost average declination.

2.2 Instruments

The bulk of observations aiming at the detection of variable stars with periods of two to several hundred days was carried out with the 80 cm telescope¹ of Wendelstein observatory² and the CCD camera MONICA. Additional observations were done with the 1.23 m telescope and its CCD camera at Calar Alto observatory.

2.2.1 The 80 cm Telescope at the Wendelstein Observatory

The Wendelstein 80 cm telescope is a fork-mounted Ritchey-Chrétien system (RC) with a Cassegrain focal station. It has a focal length of $f = 9.9$ m and a primary mirror diameter of $D = 0.8$ m resulting in a f -ratio of $f/D = 12.4$. The free aperture is $A = 0.59$ m², and the unvignetted field-of-view diameter $\varnothing = 125$ mm $\approx 0.72^\circ$. The system has a plate scale of 20.8"/mm. [Barwig et al., 2007]

2.2.2 The CCD Camera MONICA

The MONochromatic Image CAmera (MONICA) is an instrument developed for the 0.8 m telescope of Wendelstein observatory. It was specifically designed to allow high precision narrow-band imaging by means of temperature controlled interference filters [Roth, 1993]. Now, it is used almost exclusively for broadband imaging. MONICA is equipped with a Tektronix 1k \times 1k CCD which has 24×24 μm^2 pixels delivering a pixel scale of 0.5"/pixel when mounted on the 80 cm telescope. The broadband filters used for *VarStarDwarves* were Roeser *BV*, Roeser *R2*, and "Johnson" *I* (Fig. 2.1). [Barwig et al., 2007]

2.2.3 The 1.23 m Telescope at the Calar Alto Observatory

The Calar Alto 1.23 m telescope is a German-mounted Ritchey-Chrétien system with a Cassegrain focal station. It has a focal length of $f = 9.8571$ m and a primary mirror diameter of $D = 1.23$ m resulting in a f -ratio of $f/D = 8$. The free aperture is $A = 0.92$ m², and the unvignetted field-of-view diameter $\varnothing = 258.1$ mm $\approx 1.5^\circ$. The system has a plate scale of 20.9"/mm. [Marien et al., 1986]

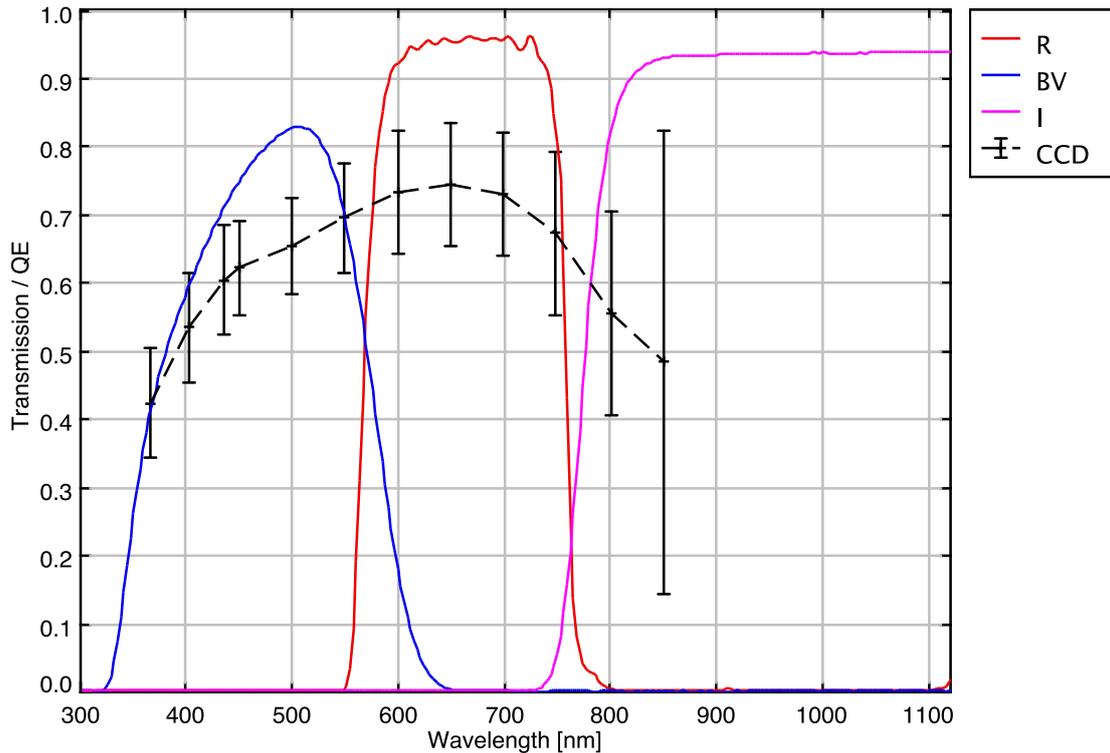

Figure 2.1: The wavelength dependent quantum efficiency (QE) of MONICA’s CCD and the transmission of “her” filters used for the *VarStarDwarves* project: CCD Tektronix 1k×1k, 24 μm pixel; Roeser *BV* / 3 mm BG39, Roeser *R2* / 3 mm OG570 + Calflex_X, “Johnson” *I* / 3 mm RG780. The CCD cutoff *I*-band filter is ill determined, i.e. Johnson not at all.

2.2.4 The 1.23 m CCD Camera

The Calar Alto 123 CCD Camera is equipped with a Site $2\text{k} \times 2\text{k}$ CCD which has $24 \times 24 \mu\text{m}^2$ pixels delivering a pixel scale of $0.5''/\text{pixel}$ at the CA 1.23 m telescope. The system is equipped with a motor controlled filter wheel. The filter applied for *VarStarDwarves* were more or less standard Johnson [e.g. 1965] broad band filters *B*, *V*, *R*, and *I* (Fig. 2.2). [Thiele, 2007]

¹“**TELESCOPE**, n. A device having a relation to the eye similar to that of the telephone to the ear, enabling distant objects to plague us with a multitude of needless details. Luckily it is unprovided with a bell summoning us to the sacrifice.” [Bierce, 1906] Modern telescopes are usually equipped with the formerly neglected bells.

²“**OBSERVATORY**, n. A place where astronomers conjecture away the guesses of their predecessors.” [Bierce, 1906] Of course this blasphemy does no longer hold in modern astrophysics which is strict deductive science based on solid findings through unambiguous experiments ... almost. (Those experiments are carried out mostly with telescopes equipped with bells, see footnote 1.)

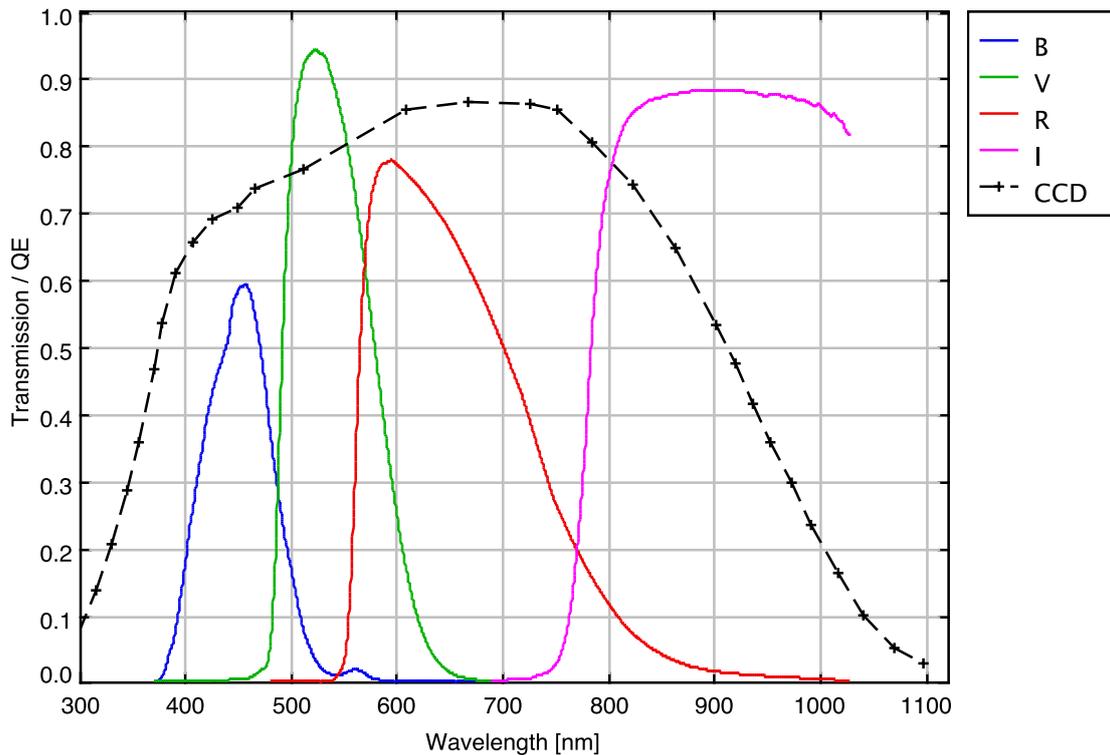

Figure 2.2: The wavelength dependent quantum efficiency (QE) of Calar Alto 1.23 m camera’s CCD and the transmission of its filters used for the VarStarDwarves project: CCD Site 2k×2k, 24 μm pixel; Johnson *B* / 1 mm BG12 + 1 mm BG18 + 2 mm GG385, Johnson *V* / 2 mm BG18 + 2 mm GG495, Johnson *R* / 2 mm OG570 + 2 mm KG3, “Johnson” *I* / 3 mm RG780. The CCD cutoff *I*-band filter is the same as MONICA’s and therefore also ill determined, i.e. Johnson not at all.

2.3 Improvements to the Observational Performance

Great efforts went into several projects to improve observations at our “home” telescope at Wendelstein Observatory. Besides developing a new CCD camera (Sect. 3) we upgraded the telescope and camera infrastructure to enable remote operation, while aiming for full robotic operation as the final goal.

2.3.1 Dome, Telescope & Environment

Encouraged by the success of simple improvements³ we⁴ continued:

³I.e. installing a second door in the dome to boost ventilation and shielding MONICA with a Faraday cage from EM radiation of the nearby radio broadcast station [Gössl, 1998, Sect. 2.2.2].

⁴“We” in the following list were mainly Heinz Barwig, Arno Riffeser, Jan Snigula, and me. (And, yes, especially the painting and flooring!)

- A high performance Internet connection now allows immediate access to astronomical Web tools as well as to big storage archiving facilities. It also enables off-site personal to offer service at short notice when encountering software problems. Finally, it is mandatory for remote observations.
- A fibre wired network in addition to uninterruptible power supplies coupled with isolating transformers minimises the damages caused by frequent lightning.
- A *Devil-Linux* [Eng, 2006] based Firewall protects the observatory LAN.
- A temperature and humidity sensor with a network interface has been installed inside the dome.
- A new emergency power generator can overcome 3 days of power outage.
- The installation of webcams in- and outside the dome building and on the telescope improved overall telescope control.
- An EM-shielded electronics laboratory allows on-site maintenance of electronics despite the strong immission of the nearby radio station (≈ 20 V/m in the UHF and VHF bands altogether) and therefore minimises down time.
- To minimise scattered light illumination effects mostly on twilight flat field calibration (Sect. 4.2.6) and “bright time” images⁵ we floored the Dome building in black. For the same reasons we also painted the inner side of the dome slit with black colour.
- Air conditioning was installed to improve the “dome-seeing⁶” situation.
- To further improve temperature control we “whitened” the exterior of the telescope building.
- We realigned the telescope mirrors [Lang, 2007] to overcome the well-known problem with RC systems, i.e. decentre coma. Regular mirror alignment control is now part of the maintenance schedule.
- Finally, after the required hard- and software updates had been finished, we relocated the observers from the storey directly below the telescope to a more remote room in order to further decrease the heating of the dome.

The improvements achieved for the local seeing⁶ situation are most impressive: Fig 2.3 compares the situation for winter 1997/1998 season [Gössl, 1998], i.e. the first run of the WeCAPP campaign [Riffeser et al., 2001], with 2002, when the *VarStarDwarves* campaign peaked, and

⁵Nights with increased skylight background because of moon light.

⁶A temperature gradient between in- and outside the dome blurs astronomical images because of refraction variances in the turbulent temperature boundary layers.

⁸The point spread function (PSF) describes the intensity distribution of a point source in the image plane. Its full width half maximum (FWHM) is a suitable quantity for imaging quality assessment.

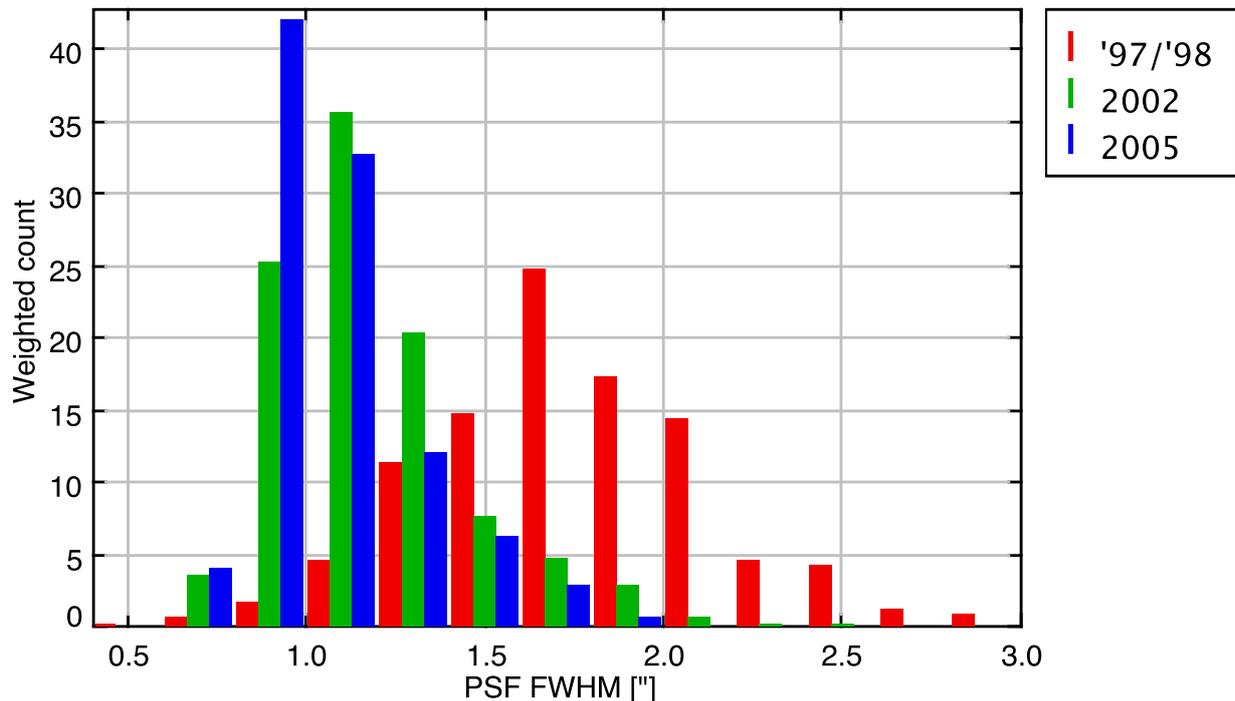

Figure 2.3: Distribution of MONICA / 80 cm WST imaging point spread function (PSF) full width half maximum (FWHM) measurements⁸ in the *R*-band for 1997/1998, 2002, and 2005. (Bin size is 0.2'') The data are all normalised to unity airmass and 100 measurements. In 2005 almost half of the observations had PSF FWHM below 1'' and about 75% were below 1.2'' whereas merely two third were below 1.8'' in the winter of 1997/1998. Note that the Nyquist [1928] rate of MONICA at the Wendelstein 80 cm telescope is $\approx 1''$.

2005, the last year with data included in this thesis. The “seeing” statistics mode improved from about 1.7'' in 1997/1998 to about 1.1'' in 2002, and even below 1.0'' in 2005. The huge gain in image resolution translates directly into an improved signal-to-noise ratio (S/N), especially for crowded field photometry. Here, the relation is linear, i.e. the 2005 images excel the '97/98 images by 50%.

The observing environment is being further improved by a webcam based all-sky cloud monitor and by the installation of an additional 40 cm telescope suitable for atmospheric extinction monitoring via standard stars observations [Lang, 2007].

2.3.2 Software – Telescope & Camera Controlling Systems

In the course of my diploma thesis [Gössl, 1998] I deployed a new camera controlling program supporting menu and simple scripting control of all camera features, log file generation, FITS data format images⁹, an autofocus function, and already accessing telescope data. We (mainly

⁹Wells et al. [1981].

Jan Snigula and me) continued to upgrade the telescope and camera controlling software.

Telescope Control Software

In order to allow remote access to the telescope and to give means for better integration of the observing software the existing telescope software has been expanded and complemented by client / server architecture applications. They communicate utilising an Beck IPC Microcontroller [Bec, 2006] as a relay between the observatory LAN and the telescope's serial interface and hardware switches. The details are given in Snigula [2006, Chap. 7].

Offset guiding – Auto-dither

The offset guiding unit of MONICA is built of a commercial CCD camera (SBIG ST-7) which can be positioned by the same motor controller as the filter wheel of MONICA. A radial translation stage may be rotated by 270 degrees on an azimuth drive. In addition a motor driven adjustable diagonal mirror on the radial stage images a 1:1 subfield onto the guiding camera and allows for focusing as well as for compensation of the focal plane curvature. While the motor controls were already accessible from the MCS [Gössl, 1998, Sect. 2.3.2] the camera and the actual guiding still had to be controlled by a Windows PC. This “solution” was very unstable when encountering rapidly changing observing conditions¹⁰ and also involved very long parallel interface cables which together with the high immission of a nearby radio broadcast station again lead to an unreliable behaviour. Also the field selection for “Windows-”guiding was restricted to three azimuth positions of the camera. Therefore we replaced the Windows PC with a small embedded Linux PC directly attached to MONICA. In order to relay the guiding camera control I wrote a server application for this Linux PC which makes all camera functions available via network and provides a flexible and robust guiding scheme. All server functions and configuration options are detailed in App. A. A graphical user interface based on the cross-platform application development library Qt [Haavard and Chambre-Eng, 2007] can be used to control the guider. This also enables remote control of the guiding unit via Internet. In addition the azimuth position of the camera is directly updated by the MONICA Controlling Software (MCS) allowing to use the complete 270 degrees for guide field selection.

When trying to minimise effects of defective detector pixels and the impact of the S/N ratio of calibration images¹¹ on the overall S/N ratio of an image stack a technique called “dithering” is the solution: Dithering slightly moves a detector relative to the observed field between subsequent exposures to ensure that the same region of that field is probed by different detector elements. Of course dithering has to be implemented in a manner that it does not interfere with guiding. Actually guiding can even be used to perform the dithering procedure if it can be triggered by the primary camera control system which is exactly the way I went: The MCS has

¹⁰E.g. even small clouds passing by aborted guiding and the commercial guiding software did not allow any changes in the guiding scheme.

¹¹See Sect. 4.2.6 for flat field calibration. For actual calculations quantifying differences in S/N of dithered and undithered stacks see Gössl and Riffeser [2002, Sect. 2.2].

Table 2.2: The combined filter throughputs + CCD sensitivity of the 7 MONICA filters relative to the twilight sky without any filter.

filter	no filter	<i>I</i>	<i>R</i>	<i>BV</i>	<i>H_α</i>	<i>V</i>	<i>B</i>	<i>U</i>
throughput τ	1.0	0.2	0.4	0.4	0.05	0.2	0.2	0.05

implemented an auto-dither toggle which, if turned on, triggers dithering during readout of the MONICA CCD.

Automated twilight flat field calibration acquisition

Obtaining a “perfect” flat field calibration image for every night and every filter is mandatory (Sect. 4.2.6). The Tyson and Gal [1993] twilight formula describes the time dependency of the brightness of the twilight sky. After adjusting for the observatory’s latitude resulting in a table for the twilight length for every day of the year it can be used to adjust exposure times to achieve flat field images with a more or less constant flux. But full automation requires even more than that: To achieve an optimal flat field series the maximal number of calibration images for a given sequence of filters, which is a complex function of their consecutive throughputs and the CCD sensitivity within that passband in respect to the colour of the sky, has to be predicted beforehand and distributed among them. In addition, images within one filter band have to be dithered by an offset big enough to avoid stars having an impact on a stacked flat field (Sect. 4.2.6).

After implementing the necessary prerequisites¹² I have derived a working scheme by evaluating existing “optimal” flat field series performed by experienced observers. The empirically determined constraining limits for the series are:

- The minimal exposure time is 5 s to minimise systematics caused by the shutter movement.
- The maximal exposure time is 600 s to limit the impact of cosmics and stars on the stacked flat field (Sect. 4.2.6).
- The maximal flux (i.e. the median flux of the flat) is 63488 ADU which is already enough below the saturation level of 65535 ADU.
- The minimal flux is 16384 ADU.
- The “optimal” flux which gives both, enough flux per flat and enough total flats, is about 28672 ADU.
- Multiple filters in a series are sorted due to their throughput (Tab. 2.2), i.e. less throughput corresponds to brighter sky.

¹²Telescope offsets controlled by the camera software, date dependent twilight flux prediction for Wendelstein, maximum number of flat fields per filter prediction, automatically constructing the filenames fulfilling the naming convention sky_filter_yymmdd_###.fits, etc.

- A flat field series starts centred on a blank field. Offset the pointing by 20'' in declination and right ascension between every image (flat field dither offset). Change direction of the offset after the every “odd” filter change (first, third, fifth, etc.).

These constraints are applied to the following procedure:

1. Calculate the number n of achievable images per filter:

$$n = \frac{15}{N} \left(1 + \sum_{i=2}^N \|T_i - T_{i-1}\| \right) , \text{ with} \quad (2.1)$$

N = number of filters in the series,

T_i = relative throughput of a filter band compared with no filter, and

$i = \{U, B, V, H_\alpha, BV, R, I, \text{nofilter}\}$ (Tab. 2.2).

2. Capture 2 s pre-flat series images with a window readout of the centre 100×100 pixel region¹³ until the sky is bright or dim enough to start the series: For dusk the predicted flux for the minimal exposure time must be less than the maximal allowed flux; for dawn¹⁴ the predicted flux for the maximal exposure time must be more than the minimal required flux.
3. Calculate the next exposure time Δt_i with a modified Tyson and Gal [1993] twilight formula:

$$\Delta t_i = \frac{\ln \left(a^{t_i - t_{i-1}} + A \left(\ln a^{\Delta t_{i-1}} - 1 \right) \right)}{\ln a} - (t_i - t_{i-1}) , \text{ where} \quad (2.2)$$

Δt_{i-1} = the previous exposure time,

$t_i - t_{i-1}$ = the time span elapsed since the previous exposure start,

$A = \text{flux}_{\text{optimal}} / \text{flux}_{i-1}$, the amplification factor needed to derive an optimal flux level considering the flux level of the previous exposure, and

$a = 10^{\kappa/\tau}$, with

$\kappa = 0.094 \text{ min}^{-1}$ the empirical normalisation factor for the exponential twilight brightness law derived by Tyson and Gal, and

τ = actual length of twilight in minutes which has to be determined for the latitude of Wendelstein and every day of the year. If the derived exposure time is beyond the limits reset it to the nearest limit. Start an exposure.

4. During CCD readout move the telescope by the flat field dither offset. If there is an “odd” filter change coming up, reverse offset direction for the next offsets.

¹³To reduce the overhead from 90 s for a full image to less than 20 s for the centre 1% window.

¹⁴“DAWN, n. The time when men of reason go to bed. Certain old men prefer to rise at about that time, taking a cold bath and a long walk with an empty stomach, and otherwise mortifying the flesh. They then point with pride to these practices as the cause of their sturdy health and ripe years; the truth being that they are hearty and old, not because of their habits, but in spite of them. The reason we find only robust persons doing this thing is that it has killed all the others who have tried it.” [Bierce, 1906] Quot erat demonstrandum: Observing astronomers are men of reason.

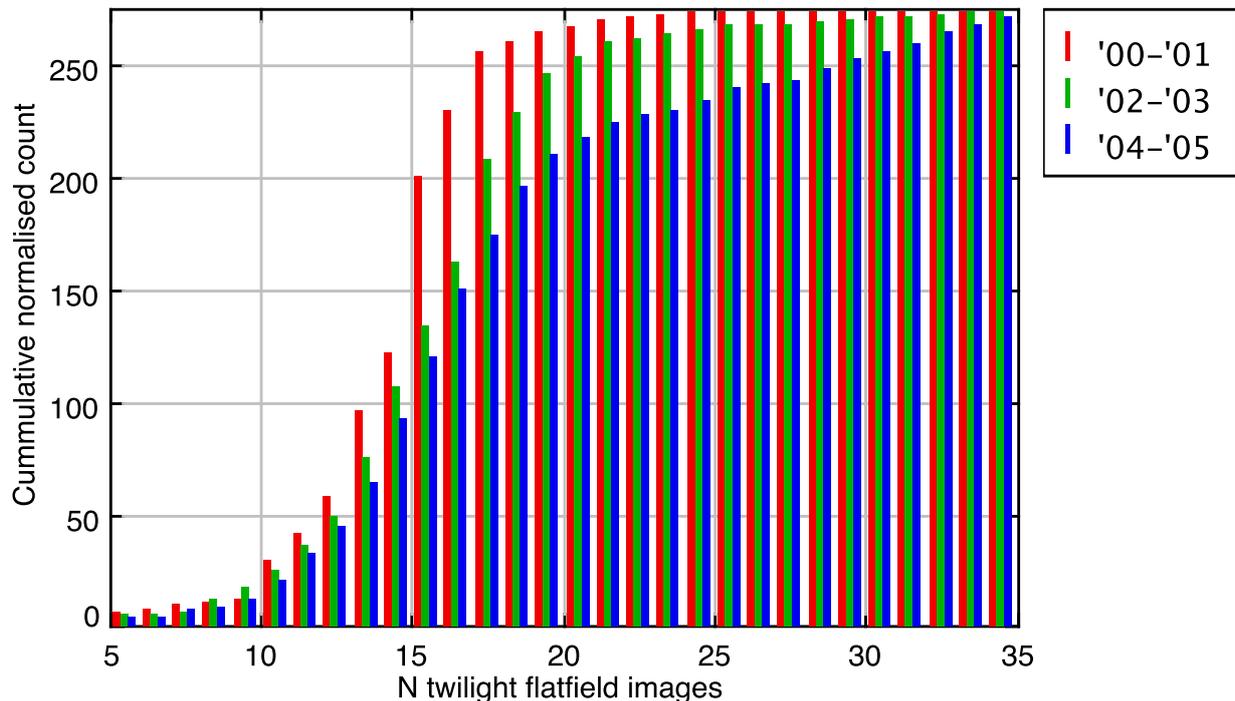

Figure 2.4: The number of flat field calibration images achieved per night has continually increased. First by experience (red to green), then by introducing the auto-flat procedure (green to blue). The cumulative histogram counts the number of twilight flats normalised to the average of 280 clear nights per biennium. The later the histogram saturates or the slower it grows the more flat field images were recorded. Example 1 (blue 250 / 29, green 280 / 29): In '04-'05 for 250 (of 280) nights no more than 29 twilight flat field images could be obtained which implicitly means that for 30 nights more than 29 “flats” were recorded; in '02-'03 no night had more than 29 flats. Example 2 (blue 150 / 16, red 225 / 16): In '04-'05 for 130 (normalised) nights more than 16 “flats” were obtained whereas in '00-'01 only 55 nights surpass 16 “flats”.

5. If the current filter is done and there are still filters on the list, select the next filter.
6. Whenever the flux actually was too high before the end of the series or the predicted flux after a filter change would be too high (using the exposure time derived for the previous filter) repeat a pre-flat to readjust the exposure time.
7. Go back to 3, but repeat the last filter in the series just unless the abort conditions for dusk or dawn respectively are met. For dusk: The previous exposure was with maximum exposure time and is below the minimum flux threshold. For dawn: The previous exposure was saturated and the following pre-flat is also saturated.

Fig. 2.4 displays the gain in flat field images per night. (See caption and compare the blue bars to the green and red ones.) The average number of “flats” per twilight increased from 14.34 in '00/'01 over 15.87 in '02/'03 to 17.56 in '04/'05, i.e. by more than 20% overall.

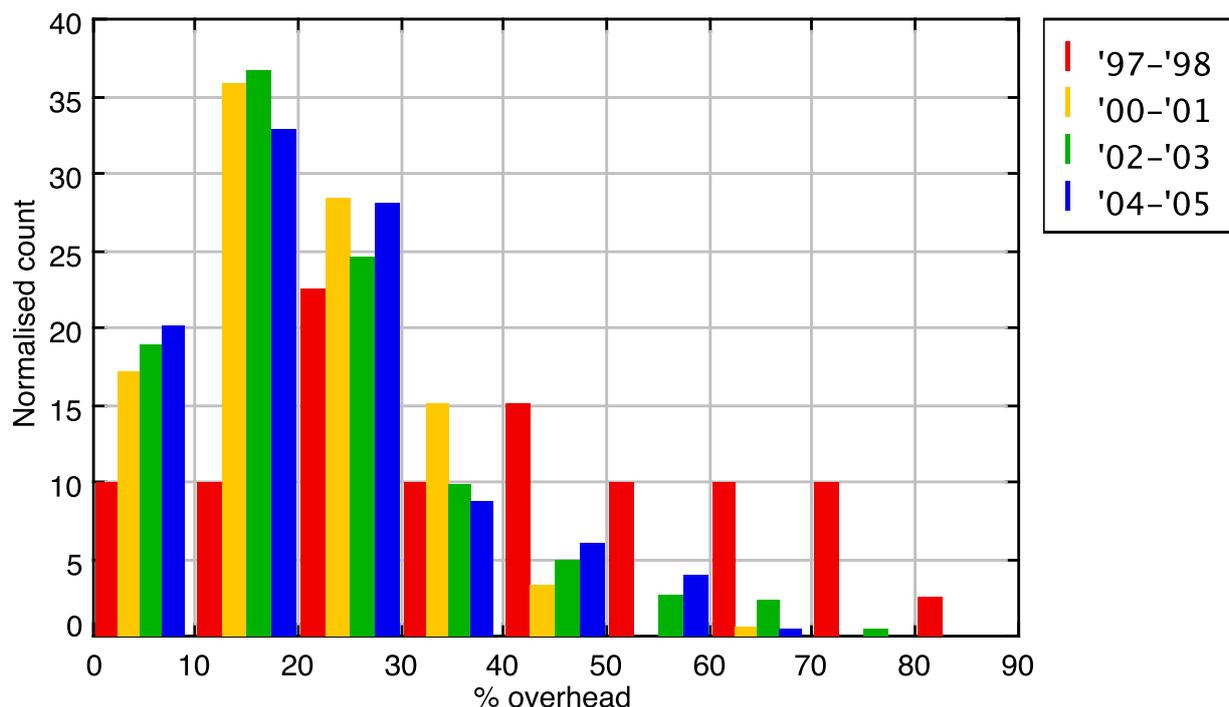

Figure 2.5: The MONICA imaging overhead (excluding pure camera overhead as CCD wipe or CCD readout). The overhead is the percentage of “idle” time of the camera in the span between the first and the last science night sky image of each night. Observations performance has been greatly improved until 2001 and remains on that high level since. In '97/'98 about 50% of the observations had less than 40% overhead (i.e. summing up the four “0, 10, 20, and 30% bins”) whereas more than 90% of the observations did so since 2000. The data of 1997/1998 and partially from 2000 had to be put together manually, because no automatic logs were available. Nights with less than 30 minutes “shutter-open” time and guest observers who produced in average more than 50% overhead were ignored. Observation breaks longer than an hour were also put off the record, because they are presumably due to clouds passing through.

2.3.3 Log files, Webcam Movies, and Backups

To replace handwritten observation reports and manual DAT tape archives by more contemporary means I installed additional network services: Instrument and observer log files, logs of the dome environment and the public weather¹⁵ station messages, together with small movies of

¹⁵“WEATHER, n. The climate of the hour. A permanent topic of conversation among persons whom it does not interest, but who have inherited the tendency to chatter about it from naked arboreal ancestors whom it keenly concerned. The setting up official weather bureaus and their maintenance in mendacity prove that even governments are accessible to suasion by the rude forefathers of the jungle.

Once I dipt into the future far as human eye could see,
And I saw the Chief Forecaster, dead as any one can be –
Dead and damned and shut in Hades as a liar from his birth,

the terrace and the 80 cm telescope finder webcams are automatically collected and placed on a secure “Intranet” website which also hosts observatory documentation. All data collected is synchronised with a backup system at USM¹⁶ which again runs an automated backup process utilising the LRZ¹⁷ archive centre in Garching. The new services not only allow to evaluate observation performance more easily, they even provide means to automate surveillance procedures (Fig. 2.5, also Fig. 2.3 and 2.4).

2.4 Observational Strategies

The overall observation setup should yield a preferably homogeneous data set. Therefore the decisions to be made during observations should be few and simple to accomplish this requirement with multiple observers and observing conditions. Aiming at a limiting magnitude of ≈ 22.5 and taking into account instrumental overhead as well as the frequency of instrumental and observing artifacts (i.e. satellite trails, cosmics, focus drift, guiding failure etc.) we came up with the following observing strategy:

- A single observations series comprises 10×180 s exposures of one target in one filter.
- Since *R*-band yields best *S/N* ratio per time it is our primary filter. Additional filters to derive colours should be pursued only with good observing conditions (i.e. seeing $\leq 1.5''$, sky $\leq 60 e^-/s \text{ arcsec}^2$).
- An observations series shall be repeated if the limiting magnitude could not be reached with one run (i.e. seeing $\geq 1.5''$, sky $\geq 60 e^-/s \text{ arcsec}^2$), if necessary multiple times.
- All exposures of a single series should be dithered¹¹ to reduce the impact of pixel systematics and the flat field noise.
- Try to get as many flat field exposures as possible to avoid calibration being the limiting factor.

With a record of unreason seldom paralleled on earth.
 While I looked he reared him solemnly, that incandescent youth,
 From the coals that he'd preferred to the advantages of truth.
 He cast his eyes about him and above him; then he wrote
 On a slab of thin asbestos what I venture here to quote –
 For I read it in the rose-light of the everlasting glow:
Cloudy; variable winds, with local showers; cooler; snow.

Halcyon Jones” [Bierce, 1906]

2.5 Observations – Database

Tab. 2.3 displays the maximum covered time span from 1999 to 2005 and the number of observed nights per filter / site for each of the observed candidates. After data reduction (Sect. 4) nights with very bad observing conditions resulting in significantly lower limiting magnitudes were abandoned whereas nights with many high quality images were split into several epochs (Sect. 5). One epoch is a stack of 10 to 30 three minutes exposures, depending on the observing conditions (seeing, sky etc.). Observations are still continued to expand the detectable period range to even longer periods.

Table 2.3: Maximum time span and number of observed nights per filter and instrument.

object	Δt [y]	WST - 80 cm			CA - 1.23 m

Chapter 3

AMiGo – A New, Two-Channel CCD Camera for Wendelstein Observatory

Tests of the seeing conditions at Mt. Wendelstein displayed a seeing statistics mode of 0.5'' FWHM. The telescope of Wendelstein Observatory is designed to reach an encircled energy distribution of 80% within a 0.6'' diameter over a 100 mm diameter field-of-view (FoV). The CCD-camera employed at present¹ (MONICA) does not comply with those site and telescope characteristics: Its 1k × 1k CCD with 24 μm × 24 μm pixels yields an 8.5' × 8.5' FoV with a 2 pixels / '' scale leading to undersampling even for average observing conditions. We therefore decided to build a new camera which can take full advantage of the current situation, and, at the time, will enable robotic operation. This new instrument was planned to play a major role in the VarStarDwarves project. Unfortunately many problems during the manufacturing phase of the instrument delayed the commissioning until 2007. Nevertheless, the development and building of the camera being a substantial part of my work and its construction being motivated by my PhD thesis I will give a summary of the overall camera design as presented at the SPIE conference on “*Astronomical Telescopes and Instrumentation 2002*” and published in the corresponding proceedings [Goessl et al., 2003].

3.1 Optical Layout

3.1.1 Design Goals

To specify the design goals for the camera we defined a three-level scheme of favoured characteristics, basic conditions, and acceptable trade-offs.

¹“PRESENT, n. That part of eternity dividing the domain of disappointment from the realm of hope.” [Bierce, 1906]

Favoured characteristics

The pixel scale of the instrument must be adapted to the optical performance of the telescope and the seeing of the site, which requests at least 2 pixels / 0.6". If feasible the FOV should be larger than the present one. Using high efficient CCDs and building a multi-channel camera, which also allows simultaneous multi-waveband observations, increases the telescope efficiency tremendously. A photometric shutter enables short exposures without introducing systematic errors (shutter pattern). Therefore it allows a superb twilight flatfield acquisition for every night. Including robotic operation and maintenance features, thereby minimising the need for on-site manpower, will help to guarantee a future for the observatory. Since fund raising for a new 2 m class telescope for Wendelstein observatory was successful the camera should be able to cope with a 2 m, $f/6$ telescope design without too much image degradation.

Basic design constraints

All basic conditions can be summarized in the need for a compact design: The optics must fit between the focal plane and the telescope flange, which are only 267 mm apart from each other. A massive electro-magnetic shielding for all electronics is mandatory not only because of frequent lightning but moreover to minimize the influence of the intense radio immission of a nearby radio station. The complete instrument (including controllers and EM-shielding) must not exceed a weight of 100 kg. It must apply to the telescope's Cassegrain focus and therefore fit in a volume less than 0.5 m³.

Acceptable trade-offs

Concessions may be made regarding the filter wave bands: Despite its excellent seeing conditions the observatory site displays only modest transparency and suffers from light pollution of nearby villages. The Hg lines of the street lighting add to the O[I] night-sky line in the V band. The already poor performance of atmospheric cut-off UV band filters, which is mainly due to air pollution, is also hampered by the street lighting, i.e. its UV lines. So the use of both, U and V band filters, should be avoided.

3.1.2 Design Solution

Because of the compactness constraints we decided to go for a two-channel design. The heart of our design solution is a massive dichroic beam splitter cube with two reflection prisms attached so that both beams have their focus in the same image plane (Fig. 3.1 and Fig. C.1, top). This enables us to place both CCD detectors into a single cryostat with one Cryotiger cooling unit, only. We defined the dichroic layer to build two optical channels operating in the spectral range of 400 – 540 nm and 570 – 900 nm. The camera has three interchangeable filters per channel and two independent photometric shutters. It is equipped with two LORAL/Lesser 2k × 2k CCDs with 80% peak quantum efficiency [Deiries et al., 1995, 1996, and Fig. 3.4 here], each displaying the same FOV of 10.7' × 10.7' with a resolution of 0.3" per (15 μm)² pixel.

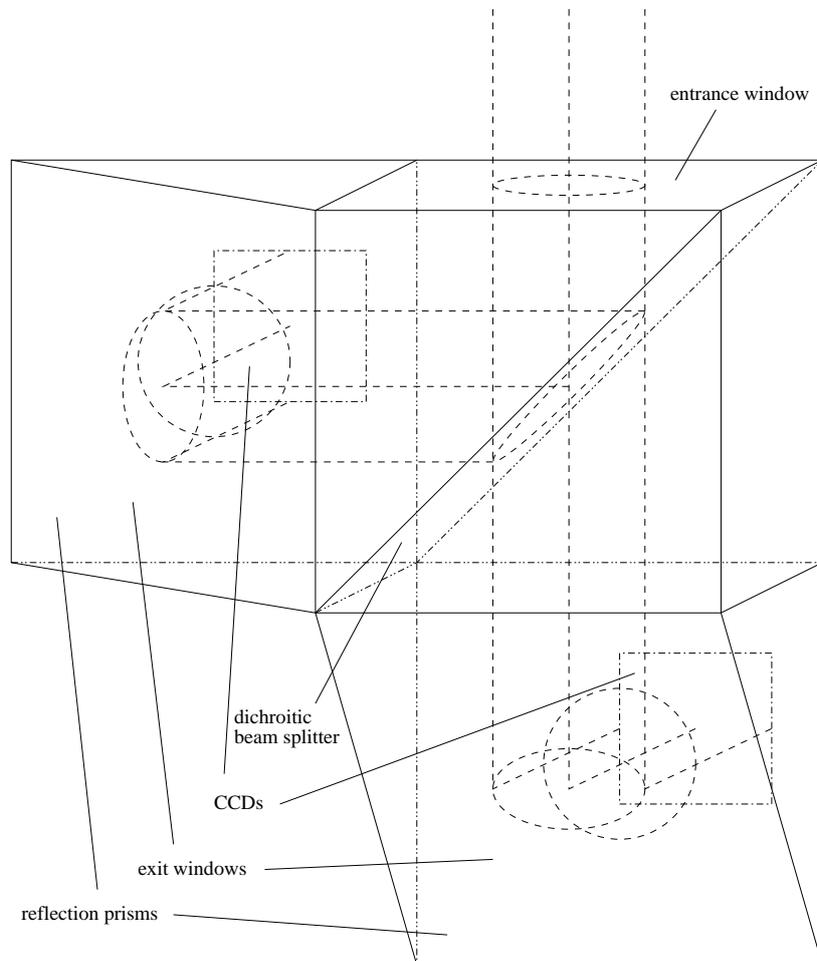

Figure 3.1: Design sketch [2:3] of the dichroic beam splitter. Light falling in from “above” is split within the $80\text{ mm} \times 80\text{ mm} \times 80\text{ mm}$ beam splitter cube in a reflected, left side, blue beam and a transmitted, downwards, red beam. Both beams are reflected by adjacent reflections prisms and leave the unit “backwards” to fall on their corresponding $30\text{ mm} \times 30\text{ mm}$ CCDs resting in the same image plane after a 60 mm gap which holds filters, shutters and cryostat windows. The 160 mm massive glass results in having a wavelength dependent focal length. This can be compensated by filters of an individually matched thickness, which are inserted between the beam splitter and the CCDs. Coordinate definition: x-axis from left to right, y-axis from bottom to top, z-axis from image/CCD to observer plane.

3.1.3 Resulting Optical Parameters

The massive design of the dichroic beam splitter and the reflection prisms elongates the focus distance by 53 mm which gives additional room for the filter and shutter modules. But it also introduces a chromatic error. The thickness of each filter has to be adjusted to compensate for the wavelength dependency of the focus length. Because of the slow f -ratio ($f/12.4$) of the

Table 3.1: AMiGo image quality as derived by raytracing simulation for the SDSS [Fukugita et al., 1996] filter set (Fig. 3.4, bottom). Radii of r.m.s. spot size (top and Fig. 3.2) and 80% polychromatic encircled energy (bottom and Fig. 3.3). Columns: respective filter, radii of airy disk (top) and diffraction limit (bottom), corresponding radii for on optical axis (central field), an average distance to the optical axis, the detector edge, and the detector corner.

field	airy disk	centre 0.0 mm	avg. 10.6 mm	edge 15.0 mm	corner 21.2 mm
filter	r.m.s. spot radius [μm]				
SDSS g	6.5	12.8	12.7	13.3	16.0
SDSS r	8.8	11.2	11.1	11.7	14.6
SDSS i	11.0	10.7	11.3	12.6	16.5
radius of 80% encircled energy [μm]					
SDSS g	9.2	19.5	18.8	18.6	19.5
SDSS r	12.2	19.4	17.7	16.7	18.6
SDSS i	14.9	18.3	17.8	17.8	20.9

telescope the intra wave band error of a single filter is rather small. Raytracing simulations of the expected image quality for the SDSS [Fukugita et al., 1996] filter set (Fig. 3.4 and Tab. 3.2, bottom) are presented in Fig. 3.2 and Tab. 3.1. Unlike a design using beam splitter plates no offcentre ghosts, astigmatism, or additional coma² are inferred. The apertures of the entrance and exit windows are baffled to meet even the demands of an $f/6$ focal ratio of a future 2 m class telescope for Wendelstein observatory without affecting the field illumination, i.e. off-field beams deflected inside the beam splitter unit are masked.

3.1.4 AMiGo Filter sets

The first AMiGo filter set was designed to mimic the standard MONICA (Fig. 2.1) and/or Johnson [1965] filters (Tab. 3.2 and Fig. 3.4 top, photos in Fig. C.1, top.). Using coloured Schott glass filters [Sch, 2004] is cheap but undermines compensating the chromatic focal length because of their very ill defined refractive indices. A second set of filters (Tab. 3.2 and Fig. 3.4 bottom) following the meanwhile standard³ SDSS system [Fukugita et al., 1996] was specified and ordered as thin film coated fused silica which has a well known refractive index. Its filter thicknesses completely compensate for inter-waveband focal length discrepancies.

²The astigmatism resulting from a beam splitter plate can be corrected with an additional plate rotated by 45° along the optical axis but with the same inclination angle as the beam splitter plate, but will show coma shaped distortions [Reif et al., 1999, Woche et al., 2000].

³For extragalactic science.

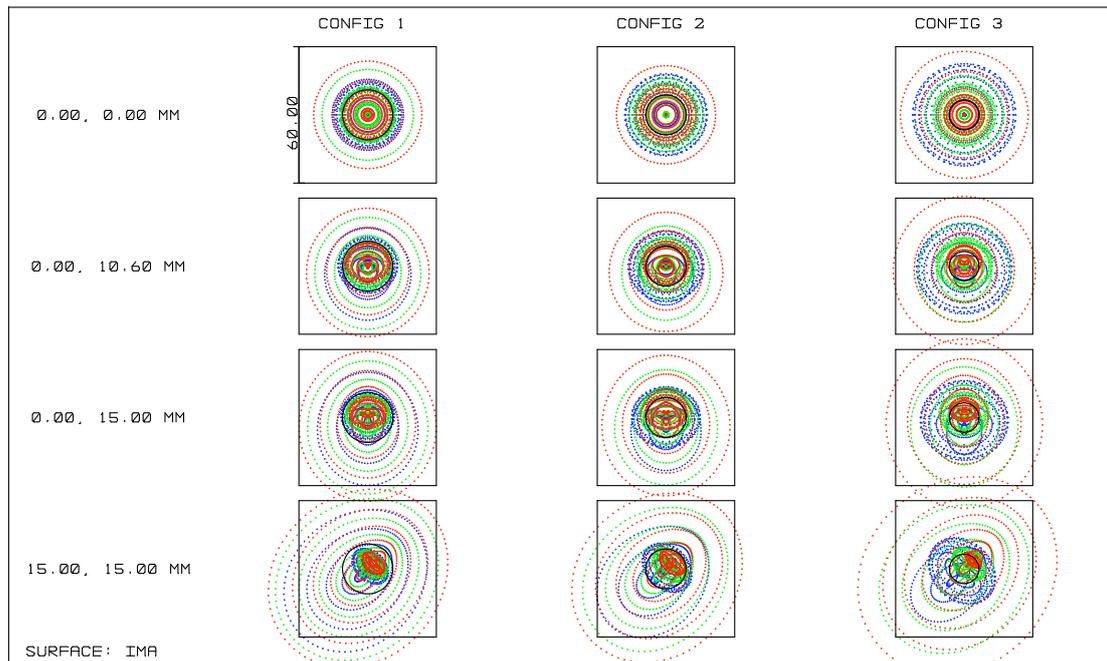

Figure 3.2: Visualisation of AMiGo image quality by raytracing spot diagrams. (See also Tab. 3.1, top.) The focus position of the image plane is adjusted to optimum within the detector area, i.e. minimising r.m.s. spot sizes. Rows: From top to bottom central field (on optical axis), average field (average distance from optical axis), detector edge, detector corner. Columns: From left to right SDSS [Fukugita et al., 1996] i (Config 1), r (Config 2), and g (Config 3) filter cases (Tab. 3.2 and Fig. 3.4, bottom). Colours: blue is short wavelength 50% transmission edge, green is central wavelength, red is long wavelength 50% transmission edge. The black ring show the airy disk. The black box has a side length of $60\ \mu\text{m}$ corresponding to 4×4 detector pixels.

3.2 Mechanical Design

The optically active parts of the camera are combined to four major units: the cryostat, a filter / shutter unit, the dichroic beam splitter unit and the offset guiding unit. All units together with controllers and computers are mounted on a basement plate, which is suited to be attached to the telescope flange. (See also design drawings Fig. 3.5 and 3.6 as well as photos in Fig. C.1 and C.2.)

3.2.1 Cryostat

The cryostat holds two CCDs placed on two independent, three-axis motorized chip mounts: Six Newfocus Picomotors enable two-axis tilt plus an independent focus adjustment for each CCD. Together with the six axis alignment of the beam splitter unit (Sect. 3.2.3) we have 12 axis alignment for two detectors, so every detector can be aligned independently. Active cooling by a

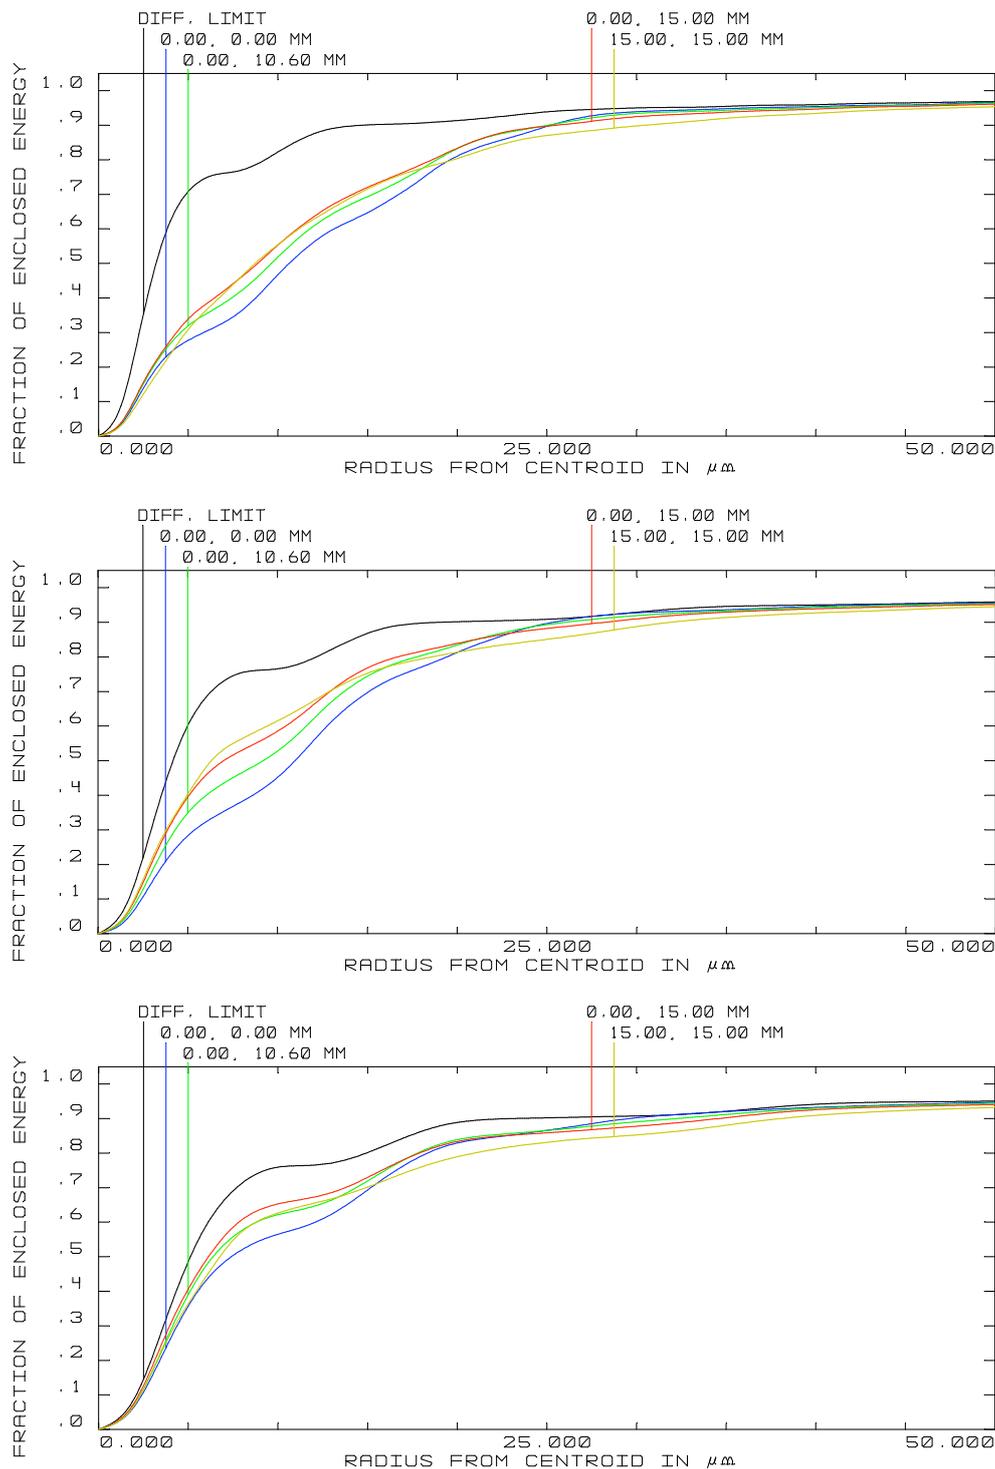

Figure 3.3: Visualisation of AMiGo image quality by raytracing simulation, i.e. polychromatic encircled energy distribution within respective filter band. (See also Tab. 3.1, bottom.) The focus position of the image plane is adjusted to optimum within the detector area, i.e. minimising r.m.s. spot sizes. Rows: From top to bottom SDSS g, r, and i filter cases (Fig. 3.4, bottom). Colours: black corresponds to the diffraction limit, blue to the central field (optical axis), green to an average field (average distance from optical axis), red to the detector edge, and yellow to the detector corner.

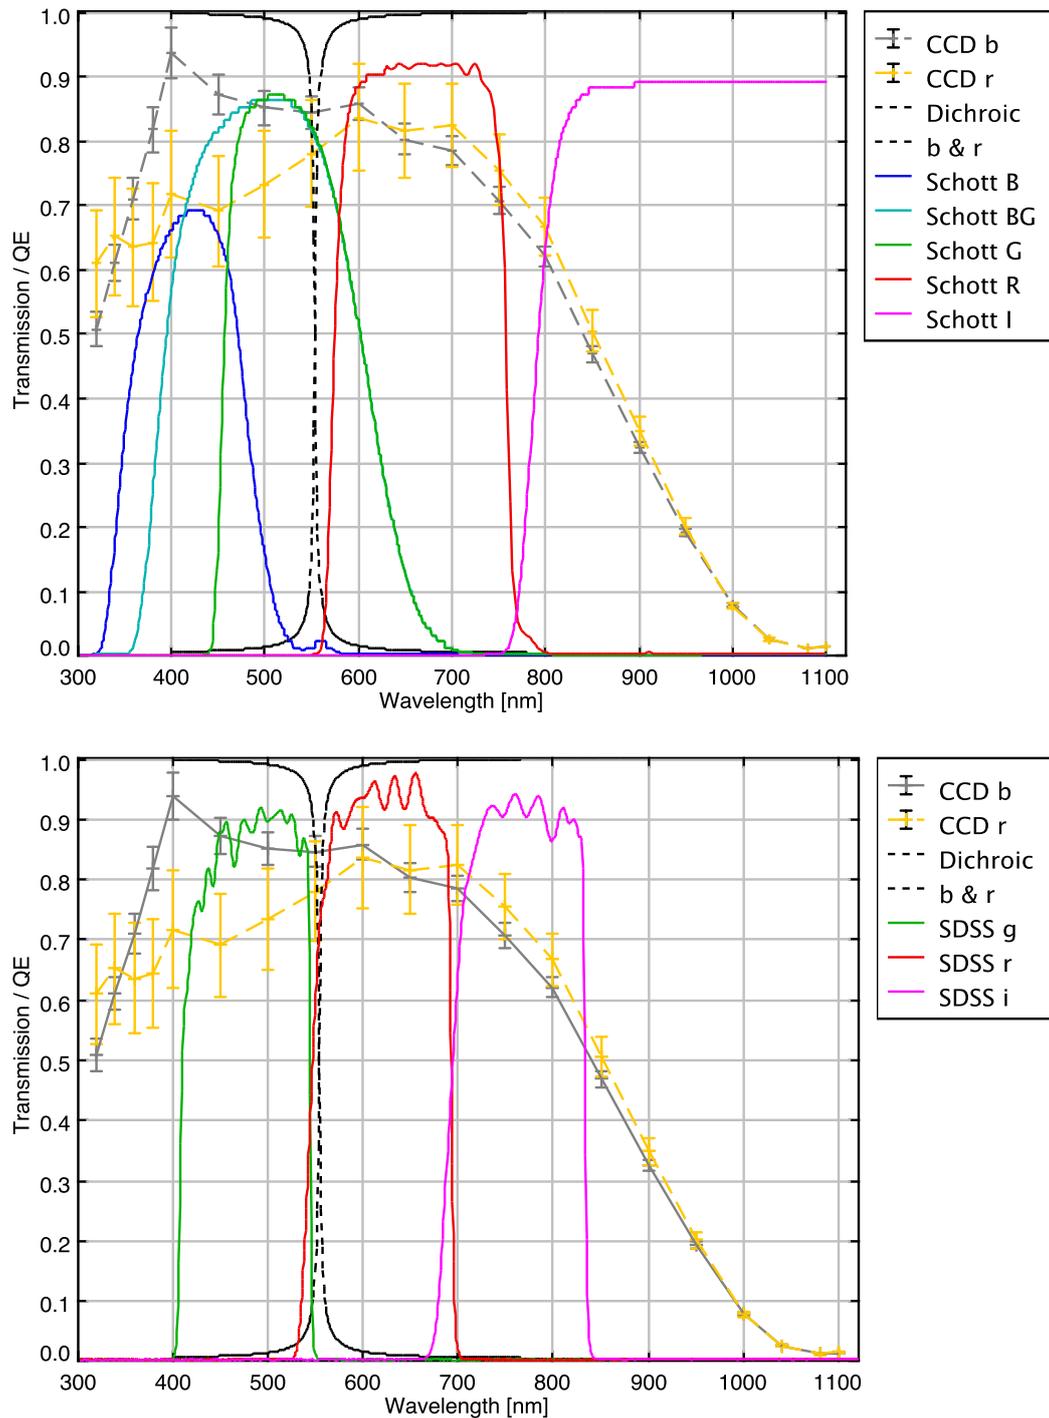

Figure 3.4: Both figures: Wavelength dependent quantum efficiency of the AMiGo LO-RAL/Lesser CCDs [Deiries et al., 1995, 1996]. One CCD (grey) shows clearly superior sensitivity in the blue bands, while the other (yellow) displays only a slightly enhanced response in the red bands. The wavelength characteristics of the dichroic beam splitter are shown as specified. Top: Throughput of the AMiGo Schott coloured glass filters as specified. Bottom: Throughput of the AMiGo SDSS [Fukugita et al., 1996] filter set as measured by its producer. The filters are made of thin coated fused silica and their thickness is adapted for a common focal plane independent of wavelength. (See also Tab. 3.2.)

Table 3.2: Filter waveband characteristics: Schott coloured glass filters [Sch, 2004], SDSS [Fukugita et al., 1996] filters, and dichroic beam splitter as specified (see also Fig. 3.4). Numbers in brackets give an estimate for the filter characteristics when combined with the beam splitter (B, BG, G) or the CCD (I).

filter name	composition	blue edge [nm]	centre [nm]	red edge [nm]
Schott B	1 mm BG25 + 2 mm BG39	349 (365)	415 (390)	482
Schott BG	1 mm BG39 + 2 mm GG395	390	499 (472)	609 (554)
Schott G	1 BG39 + 3 mm GG455	455	532 (504)	609 (554)
Schott R	2+3 mm OG570 + thin film coatings	573	651	730
Schott I	3+3 mm RG780	789	– (854)	– (920)
Dichroic beam splitter	fused silica + thin film coatings	400 – – 540	554	570 – – 900

Cryotiger cooling device provides the operating temperature of 160 K. A turbomolecular vacuum pump is permanently attached to the cryostat via an electromagnetic vacuum valve. A cryopump which has onboard heating resistors to allow cleaning cycles without requiring any additional equipment keeps the vacuum between pumping cycles. Both, active cooling and permanent vacuum control together enable robotic maintenance.

3.2.2 Filter / Shutter Unit

The complete filter / shutter module is only 40 mm thick and can easily be mounted / dismantled without interfering with any of the other units. In this way the instrument needs no optical readjustment in case filters need to be replaced. The unit holds two three-position motorized filter sliders, which are specified to reproduce their position with below μm accuracy. Each of the two shutters has two motorized linear blades to have equivalent opening and closing movements. We expect to achieve full field photometric exposures at a 0.1% systematic error level for exposure times as short as 0.1 s.

3.2.3 Dichroic Beam Splitter Unit

The beam splitter cube / reflection prism module is housed within a six-axes alignment module. Position and position angle have to be manually adjusted once by tuning micrometer screws. The rotational axes cross in one point centred within the beam splitter cube to make the optical adjustment easier. The rotational mount resides within the Cartesian translational mount which again

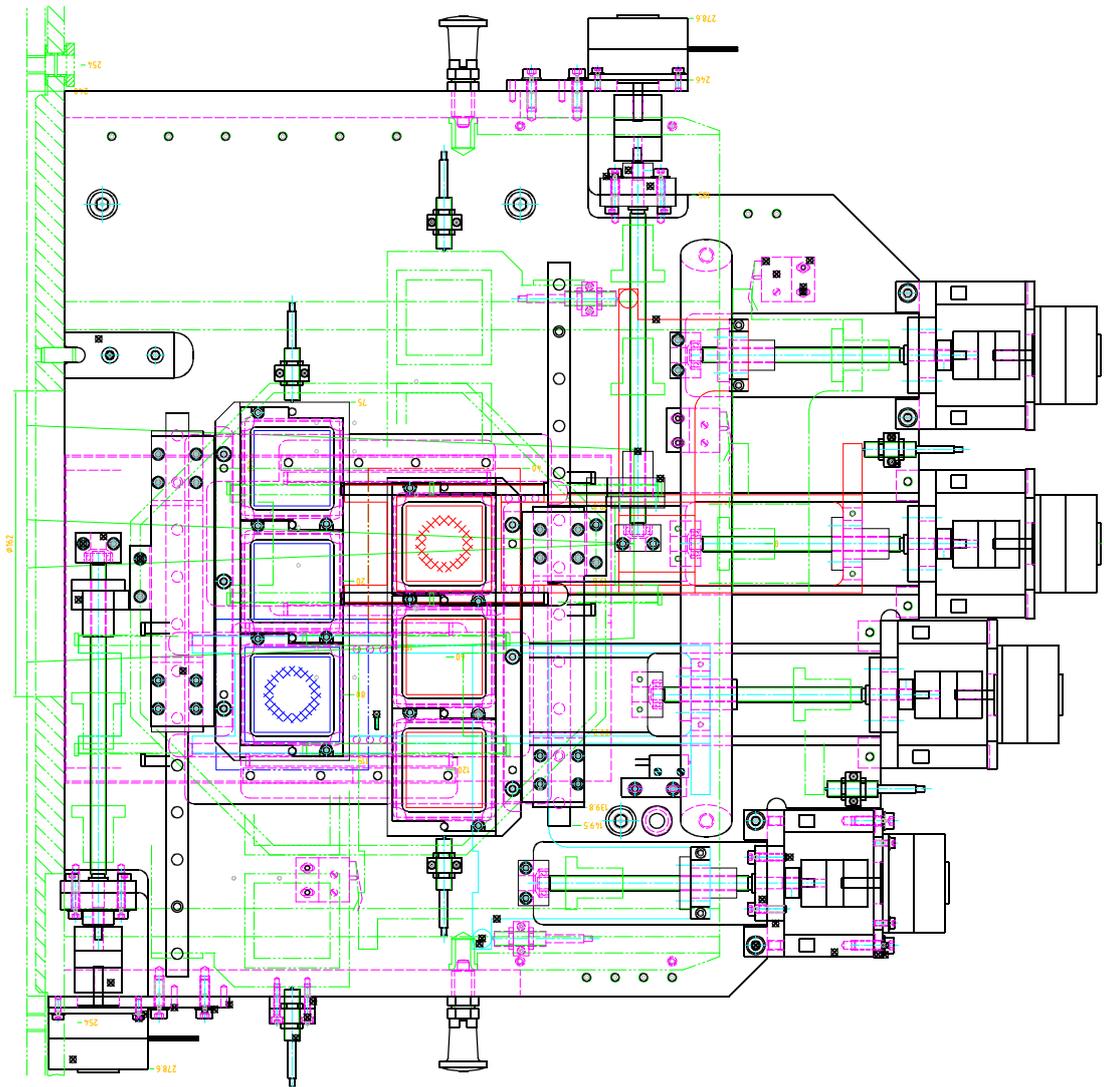

Figure 3.5: Filter / shutter module [1:4]: The design drawing shows a front view of the shutter (background) and filter slider module detailing also the motors and limit switches. The telescope flange side is left on this view.

is oriented along the major axes of telescope and instrument. In this way complex differential effects when adjusting the optics are avoided (Tab. 3.3).

3.2.4 Offset Guiding unit

The offset guide field is deflected by a mirror mounted on the beam splitter unit. The guiding camera rests on a motorized two-axis translation module which enables offset focus adjustment and an one-axis guiding field selection.

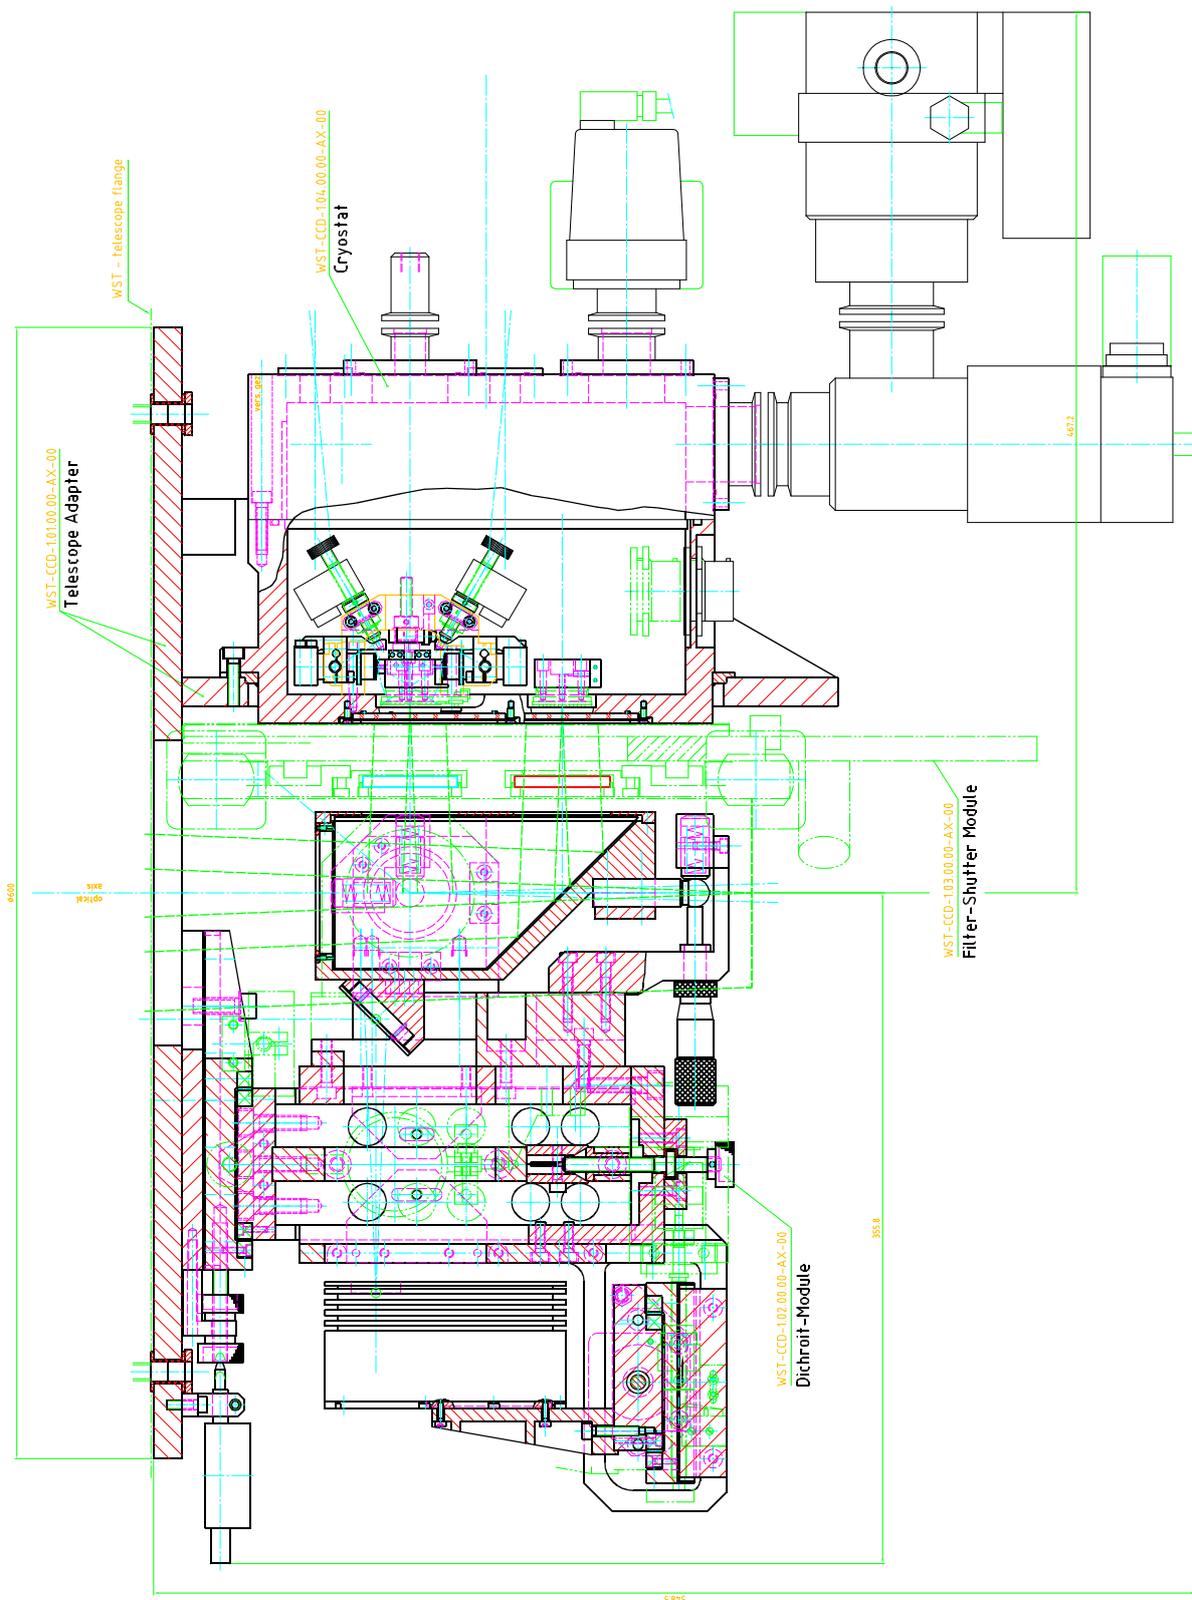

Figure 3.6: Camera overview [1:4]: The beam from the telescope enters left and is split and reflected upwards in the dichroic module, then passing through the filter/shutter module and finally focusing in the cryostat module. The beam for off-field guiding is deflected by a mirror “below” the beam splitter to the guiding camera resting on its mount at the bottom.

Table 3.3: First order adjustment recipe for the dichroic beam splitter unit. See Fig. 3.1 for coordinate definition. The relevant distances for the rotational adjustments are: rotation centre to micrometer adjustment screws = 150 mm, rotation centre to reflection prisms centres = 80 mm, and reflection prism centres to CCDs = 100 mm.

3.3 Electronic Desgin

3.3.1 CCD Controller

We use the third generation of the Leach and Low [2000] controller. It connects via fiber link to a PCI board which is installed into a PC running the controller software client, which is in our case the camera daemon server (Sect. 3.4.2).

3.3.2 Cryogenic and Motor Controllers

Stepper motors and limit switches for filter slider, shutter blades, and guiding camera movement are controlled by a CyberPak module [Cyb, 2001]. The Picomotors for the CCD alignment are controlled by a separate device driver. The vacuum and cooling devices already provide their own controlling systems. All those systems have serial interfaces which are connected to the camera network. (Sect. 3.3.4.)

3.3.3 Offset Guiding Camera

We use a ST7 CCD camera of SBIG controlled by a small Linux PC as guiding camera. This solution has been well tried and tested with the current camera system (Sect. 2.2.2 and 2.3.2).

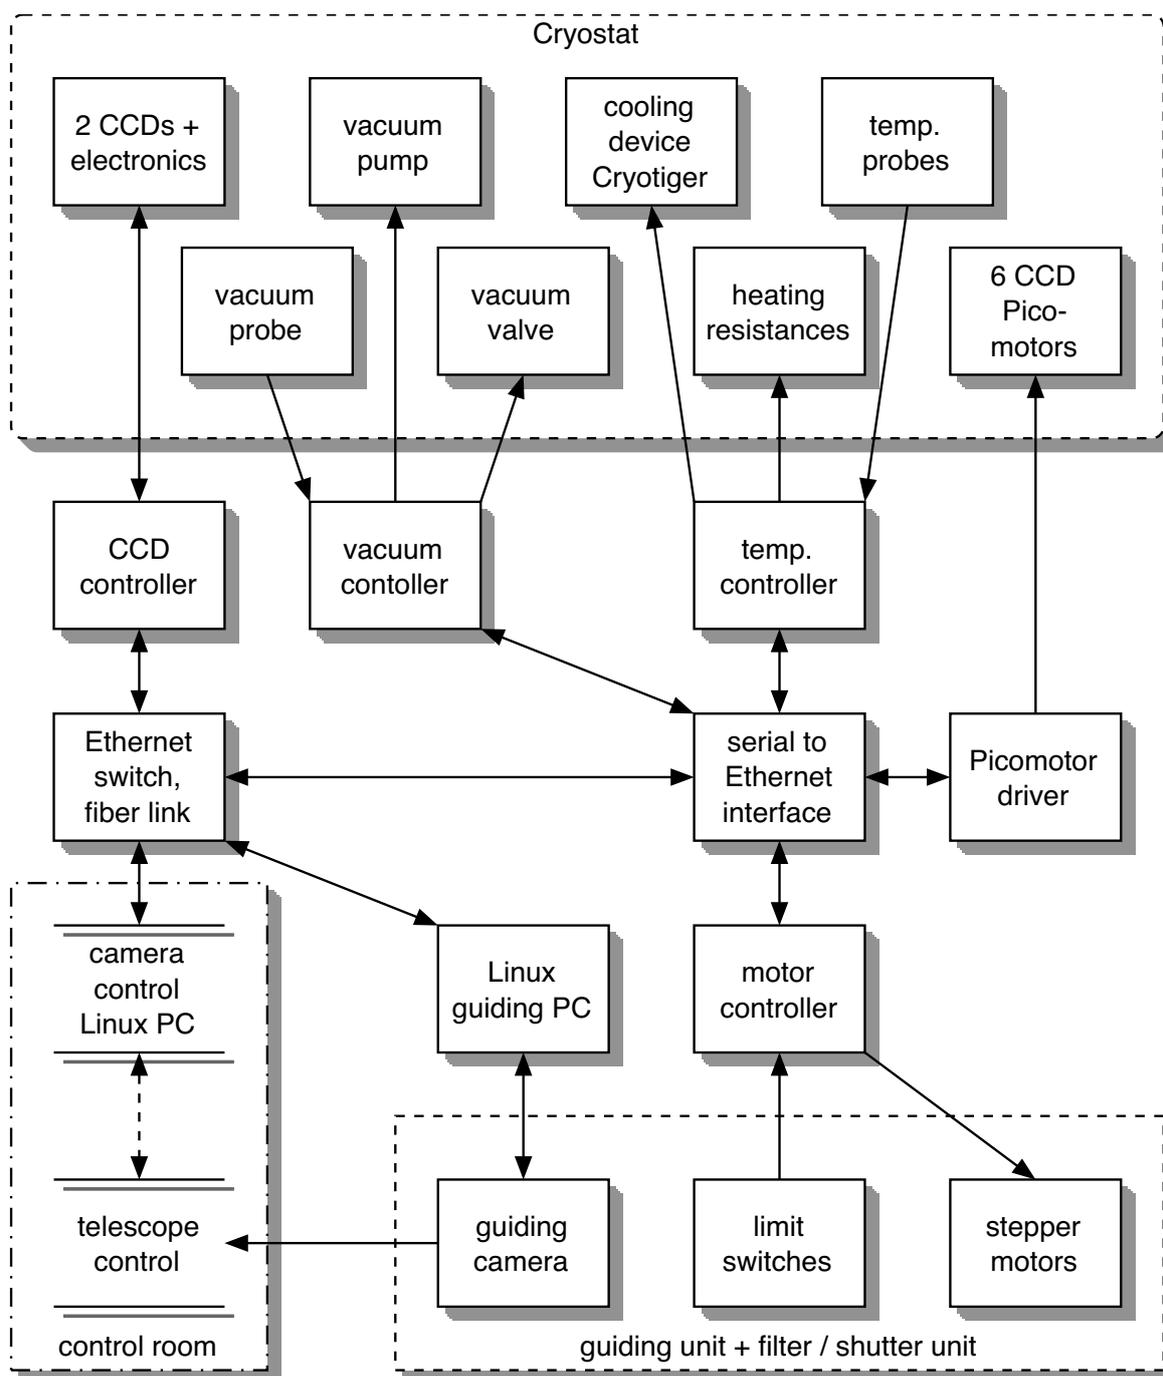

Figure 3.7: AMiGo Control Flowchart (Sect. 3.3.4): Except for the control room box, all components are mounted at the telescope and reside within the EM-shielding. The components are connected to the camera control by a fiber wire link. The camera control, which also holds the main storage unit, can be accessed via Internet.

3.3.4 Network

All Controllers have either Ethernet interfaces, or serial interfaces which are mapped to a Ethernet interface by a Beck IPC Microcontoller. The Ethernet interfaces are combined in a switch which has a fiber link connection to the main camera controlling computer. This Linux PC, which also is connected to the telescope controlling system, holds the main storage device and can be remote controlled via Internet. (See also Fig. 3.7.)

3.3.5 Electro-Magnetic Shielding

To protect the electronics of the camera against frequent lightning and the high radio immission of a nearby radio station it has a massive EM-radiation shielding. The shielding is made of 0.7 mm thick copper plate sheet and conductively connected to the mirror cell. Therefore this Faraday cage has only one major opening for the infalling light beam. Several minor openings are for wiring and a venting system, which is needed to avoid heating of the mirror cell by the camera electrics. An uninterruptible power supply (UPS) and the fiber link connection (Sect. 3.3.4) provide additional safety.

3.4 Controlling Software

The controlling software follows closely the lessons learnt by previous instrument upgrades to MONICA, its offset guiding system and the 80 cm telescope software (TCS). We implement a client / server architecture utilizing programs and libraries already developed for the TCS network [Snigula, 2006, Chap. 7].

3.4.1 Controller interfaces

The CCD controller, connected to proprietary PCI boards of a PC via fiber link, is controlled through device drivers and a software called Voodoo [Streit, 2003]. Voodoo provides low-level C-routines for all controller functions as well as an exemplary Java-GUI.

Two HS-20E Multi-Axis Indexer / Controller of Cyberpak Co. [Cyb, 2001] are controlled via serial interfaces which again are mapped through a Beck IPC device [Bec, 2006] to a TCP/IP socket. The “native” motor controller commands are very cryptic if not incomprehensible. To make things worse some commands do not even work as documented. There are 8 motors altogether which have to be controlled: 2 blades per shutter, 2 filter sliders, guiding focus and field. Since only one Indexer can be active at a time and motors have either to move sequentially or at least with identical stepping we grouped the shutters with one controller and the filter sliders and guiding with the other. This way the camera can take either “*optionally interleaving*” sequential⁴ or strictly parallel exposures. Exposures shorter than 5 seconds are accomplished by the two shutter blades forming a slit which moves through the optical beam. Besides exposures

⁴Meaning that only one shutter blade can move at a time, but e.g. one channel can make a long exposure while the other takes several short ones.

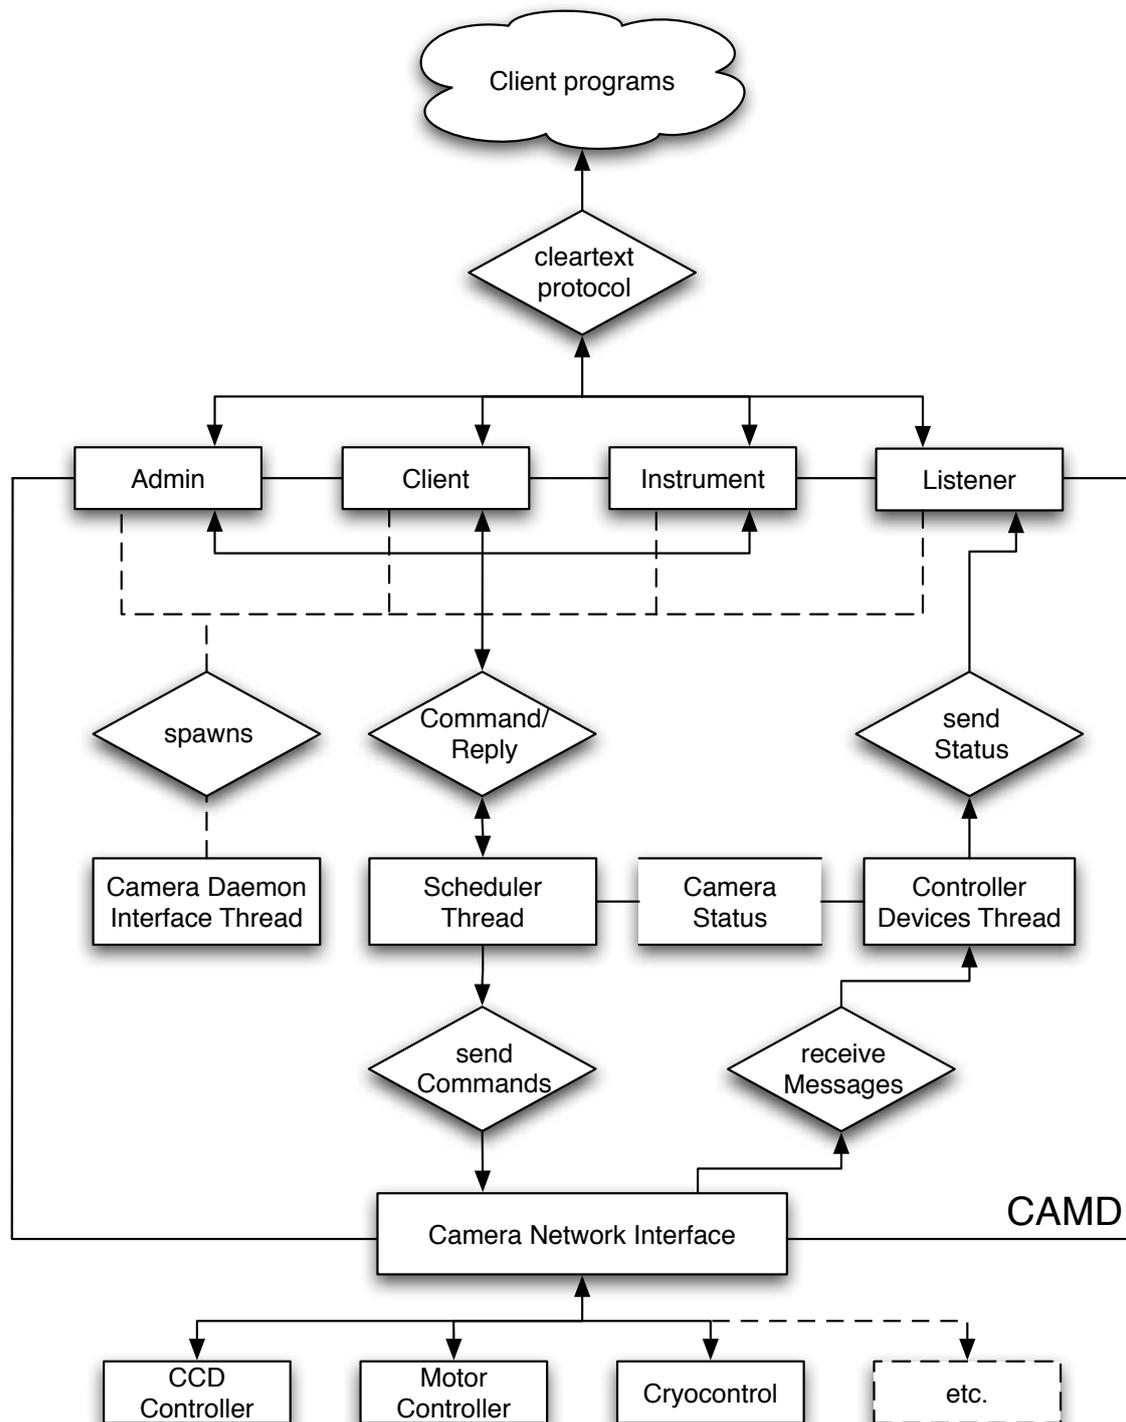

Figure 3.8: AMiGo Server Daemon (camd) overview. Top: Client interfacing; centre: Main threads and status field; bottom: Camera controller interfacing.

(and initialisation) all motors can only move one at a time. For additional information on specific motor controller commands see App. B.1.

The picomotors, vacuum and temperature control serial interfaces come all with their own proprietary protocol. They are relayed through the same Beck IPC device which also handles explicit interface multiplexing.

3.4.2 Server design and interface

The *camera daemon* (*camd*) follows closely the *TCS daemon* (*tcsd*) of Snigula [2006, Chap. 7]. The multi-threaded daemon has three principle threads (Fig. 3.8): Those are a main thread which spawns the client interface threads, a scheduler thread which takes care of executing the command queue, and a camera controller devices thread which listens for camera status messages from the different device controllers. The client interface threads supply an access hierarchy provided by separate dedicated IP ports. While *admin* access allows control even to the level of restarting the daemon or disconnecting clients, the user level client access gives only control to the camera functions. Both those access options allow only one client at a time. An additional instrument port offers a distinct subset of the camera functions to give the possibility to trigger commands from other instruments, i.e. the telescope or the guider. Finally, the listener port announces the full camera status every second and allows “unlimited⁵” connection instances. The (human readable!) syntax of all commands and listener messages is summarised in App. B.2. The internal access to the camera status representation structure is controlled by “*mutexes*” which prevent simultaneous read and write access to the same status variable. For the *camd* configuration file options and syntax see App. B.3.

3.4.3 Client design – the GUI

The *camd daemon* already allows easy access to all camera functions, e.g. by an telnet session on the client ports, and it even offers the possibility of scripting observation runs, e.g. via *shell*, *perl* or *python*. Nevertheless, a Graphical User Interface (GUI) is the easiest way to control the functions of an instrument by a computer. Therefore, we built a Qt based [Haavard and Chambre-Eng, 2007] GUI (see Fig. 3.9 for a snapshot). The GUI implements image preview, a status log view, and overall camera control, i.e. binning(s), window(s), exposure time(s), filters etc. It allows to toggle between different modes, i.e. a synchronous and an independent camera channel exposure mode, scripting mode etc. There are already builtin “hooks” for autofocus and autoflat procedures supposedly working similar to those of MONICA (Gössl [1998] and Sect. 2.3.2), but those will be more complicated to implement because of the two channel design.

⁵Of course the system operating the daemon and the available network bandwidth limits the real number of possible listener clients.

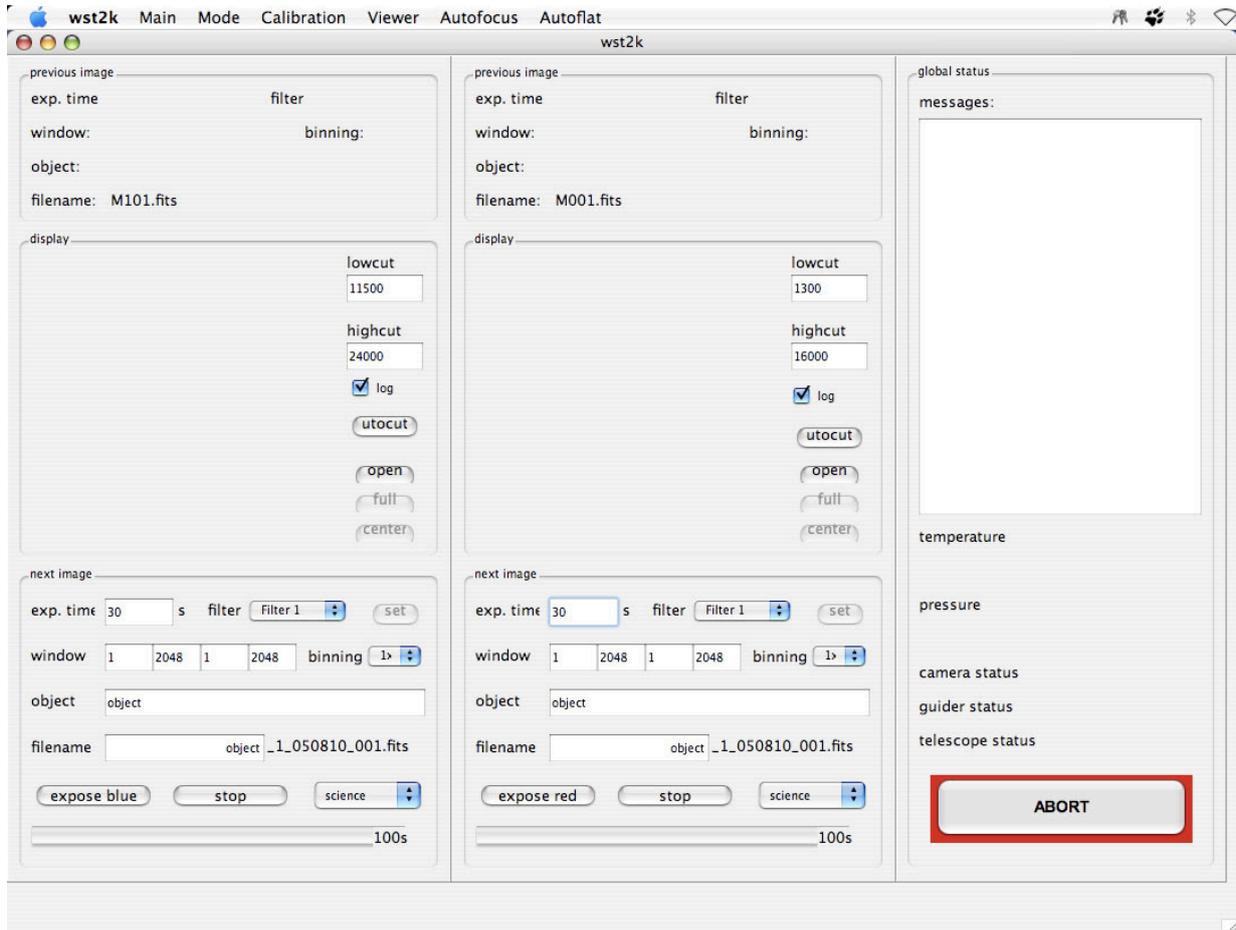

Figure 3.9: Snapshot of the AMiGo GUI: The GUI was coded utilising the Qt library [Haavard and Chambre-Eng, 2007] and therefore is cross-platform deployable. For a detailed description see text.

3.5 Deployment

AMiGo has been mechanically assembled (see also photos Fig. C.2, bottom) and passed preliminary tests of most parts. The motor controllers, camera daemon and GUI work as described above. Unfortunately, as of writing this thesis the camera still waits to see “*first light*”. Because of difficulties with the CCDs and their electronics it is currently reengineered to work with a different detector system.

Chapter 4

Data Reduction

4.1 Introduction

All observational data were processed using the techniques described in Gössl and Riffeser [2002, 2003]. Our implementation of these techniques makes heavy use of the LTL [Gössl et al., 2004], a C++ template library for high performance array calculations and data I/O. I will only summarise every step of data reduction detailed in Gössl and Riffeser [2002, 2003] adding differences and improvements accomplished since then, but not dig into all the subtleties, e.g. all the explicit formulas of error propagation; for those I defer the reader to Gössl and Riffeser [2002, 2003].

4.2 Standard Image Processing

4.2.1 $\kappa\sigma$ -clipping

Whenever averages of presumably normal distributions have to be calculated, i.e. to correct for additive constants or to divide by normalisation factors, iterative rejection of “outliers” ($\kappa\sigma$ -clipping) helps to reduce systematic errors. Asymmetric outliers can be rejected even more effectively by clipping relative to the median (and not the mean) of a sample. Whenever asymmetric outliers are a probable contaminant (e.g. particle events in the overscan region evaluated for the bias level), we apply median clipping, but, as a final iteration, calculate the average.

4.2.2 Bad-Pixel Mask

We mask saturated (and blooming affected) pixels, as well as CCD-defects (hot, cold pixels etc.). While saturated pixels will be flagged as a dominant error the CCD-defects will be corrected later (Sect. 4.2.8).

4.2.3 Bias Correction

We subtract the bias level of individual frames estimated from the overscan region and (for CA 1.23 images) a master bias, i.e. the $\kappa\sigma$ -clipped mean image of multiple bias level corrected bias frames. The bias pattern for MONICA/WST (Sect. 2.2.2) images varies over very short timescales (already between two consecutive exposures). This is because of the strong immission from a nearby radio station, so no master bias is applicable there.

4.2.4 Gain

To calculate with more meaningful numbers we multiply the flux [ADU] with the “gain” ($\frac{\text{electrons}_I}{\text{ADU}}$) of the detector system. So we have numbers in units of electrons or detected photons to start with. A propagated error (next paragraph) can now always be compared with a naive $\sqrt{\text{flux}}$ error.

4.2.5 Initial Error Estimate

The initial error estimate $\delta_I(x, y)$ for each pixel (x, y) in every image I is calculated from the pixel’s photon noise¹, the bias noise of the image (clipped r.m.s. of the overscan), and the uncertainties of bias level and bias pattern determination.

$$\delta_I(x, y) = \sqrt{\text{counts}_I(x, y) - \text{bias}_I + \sigma_{\text{bias}_I}^2 + \frac{\sigma_{\text{bias}_I}^2}{n_{\text{bias}_I}}}, \text{ where} \quad (4.1)$$

- counts_I = flux of pixel (x, y) in image I in e^- ,
- bias_I = bias of the image,
- σ_{bias_I} = we use the $\kappa(= 3)\sigma$ -clipped r.m.s. of a suitable part of the overscan as an estimation for the bias noise (i.e. readout noise),
- n_{bias_I} = number of pixels actually used for the bias determination.

Errors are propagated throughout the complete reduction pipeline with Gaussian error propagation.

4.2.6 Flat field Calibration

The relative sensitivity of resolution elements (pixels) is calibrated by applying a flat field calibration.

Since the time to get twilight flat field calibration images is very limited ($< 1\text{h}$) we also used short timed exposures where the movement time of non-photometric shutters can no longer be

¹“NOISE, n. A stench in the ear. Undomesticated music. The chief product and authenticating sign of civilization.” [Bierce, 1906] With the noise N being the denominator of the signal-to-noise (S/N) ratio civilisation greatly hampers scientific insight as can be seen in the problems of optical astronomy with light pollution or radio astronomy with radio broadcasting.

neglected. Whenever the shutter movement could be proven to have a predictable time dependency, the flat fields were deconvolved from the two-dimensional shutter function as proposed by Surma [1993]².

To achieve a high signal-to-noise ratio (S/N) for a combined flat field of an epoch we first calculate in each pixel the error weighted mean of normalised and illumination corrected twilight flat fields. After rejecting all 5×5 pixels regions where the centre pixel exceeds this mean by more than 5σ , the final calibration image is built by 3σ clipping of the remaining pixels. The illumination correction is applied twice: Per filter references-of-the-epoch are selected containing as few as possible stars but nevertheless having a comparatively long exposure time. All flat field images of a single epoch are then transformed to the reference illumination pattern by dividing through a 25-parameter 2D polynomial fit to a rigorously clipped flat field/reference ratio. This procedure is repeated adjusting all flat field epochs to an unique illumination pattern in order to minimise illumination effects on the final images.

4.2.7 Cosmic-Ray Rejection

We fit five-parameter (and three-parameter³) Gaussians to preselected⁴ local maxima of an image. Sources with a full-width-half-maximum (FWHM) along the minor axis of the fit function smaller than a threshold (chosen according to the best, i.e. sharpest, encountered point-spread-function, PSF) and, in addition, an amplitude of the fit function exceeding the expected noise by a certain factor (chosen according to the additional noise i.e. due to crowding) correspond to cosmic⁵. We replace the pixels, where the fit function exceeds the fitted surface constant by more than two times the expected photon noise with the fitted surface constant. Additionally a standard spatial median filter is applied, i.e. we replace pixels which exceed the median of the directly adjacent pixels by more than a suitable factor times the expected noise. In order to mark the “erased” cosmic as a “guess-of-flux” they get the geometric sum of their former error and the proposed naive $\sqrt{e^-}$ noise assigned as new error.

4.2.8 Approximation of bad pixel areas

Bad pixel areas would spread to larger areas after aligning dithered frames to a common positional reference and especially deep stacks, combining many images, would hence look like Swiss cheese. Therefore previously masked bad pixel areas have to be interpolated before alignment and stacking somehow. If all images had the same depth, background and PSF they could

²See also Riffeser [2006], Sect. 5.5.5.

³Most “cosmics” leave a “trail” on the detector. However, there are also many “circular hits”, and those yield a singular matrix if centred on a pixel when solving a Levenberg-Marquardt algorithm [Levenberg, 1944, Marquardt, 1963] with too many degrees of freedom. Those cases are re-fit with only surface, amplitude, and “overall” width, neglecting the second width and angular orientation parameter of the five-parameter fit.

⁴Maxima have to exceed the minimum adjacent pixel by a factor depending on their propagated error. They will still be ignored if they have more than four masked neighbours.

⁵Actually, those “cosmics” are mostly due to particle events in the detector itself and its surroundings, and only partly due to real high energy cosmic radiation.

easily be combined. Unfortunately, this is not at all applicable for ground based observations at moderate sites. We therefore replace all bad pixel areas, but saturated ones, with a distance and error weighted linear approximation of the closest neighbours. The fit box is selected as small as possible with the restriction that more than 2/3 of the fit box pixels minus the centre pixel must be valid pixels. Interpolated pixels get comparably large errors assigned derived from the supporting pixels input errors and the quality of the fit. As with the case of cosmics this helps to keep track of “guessed” fluxes and minimises its impact further on.

4.2.9 Astrometric Alignment

To register frames for astrometric alignment suitable sources have to be identified in the DG fields: In a first step the brightest not saturated sources besides those in regions of high crowding have been selected. After going through all the next steps up to convolved difference images and even variability masks (see next Sections) sources with parallaxes and/or proper motion are identified and disregarded. Unfortunately many of the brightest sources are “nearby” and have shown considerable proper motions over the more than five years of observations, especially in the fields at higher galactic latitudes⁶, leaving only few suitable sources. The actual cross identification had to be done manually for every frame by pinpointing at least two reference stars.

All frames are then shifted to a common positional reference frame for each observed field: A linear projection proves to be sufficient⁷. To achieve sub pixel alignment without degrading the images we redistribute the flux by fitting a suitable polynomial to the actual flux distribution with integral flux conservation as a side condition as described in Riffeser [2006, Sect. 5.8.6].

We link the references grid to celestial coordinates by identifying USNO stars [Monet, 1996, 1998] and calculating a WCS solution according to the FITS standard [Greisen and Calabretta, 2002, Calabretta and Greisen, 2002].

4.2.10 Signal-to-Noise Optimised Stacks

When building our per-epoch stacks, as outlined in Sect. 2.5, we maximise the S/N ratio by applying individual weights w to the input frames according to

$$w = \frac{f}{(\text{FWHM} \cdot \delta_{\text{sky}})^2} \quad , \text{ with} \quad (4.2)$$

$f =$ the flux of a bright and stable “standard” source in the field⁸,

FWHM of the position reference PSF, and

$\delta_{\text{sky}} =$ the clipped median of the “error” image.

While f scales with the overall atmospheric and instrumental throughput, i.e. the “signal”, the

⁶For obvious reasons: While the galactic disk acts almost like a rigid rotator and therefore the “disk” stars more or less corotate with the sun, halo stars follow “random” motions.

⁷Because the image planes of both, Wendelstein 0.8 m and Calar Alto 1.23 m, RC-configuration telescopes can be considered flat and undistorted for the rather small field-of-view of the cameras used.

⁸The method of measurement follows the recipe of Sect. 4.3.2.

product of the image PSF FWHM with the clipped median of the images propagated pixel errors⁹ yields a measure of the “noise” for “weak” signals which we are finally looking for¹⁰. This way, especially when fighting unstable observing conditions, we won sometimes more than half a magnitude over naive stacks. (See Riffeser [2006, Sec. 5.11] for an actual derivation of the formula.)

4.3 Optimal Image Subtraction (OIS)

Alard and Lupton [1998] proposed a method to overcome the difficulties of both, high crowding and changing observing conditions, for differential photometry¹¹: When going for time series photometry over more than a few hours ground based observations suffer from variations in atmospheric transparency, skylight background, and the image plane PSF due to atmospheric turbulence (“seeing”). State-of-the-art in the late ’90s to deal with those was to apply an iterative PSF deconvolution which also allows for a changing but “smooth” background. This scheme, implemented through packages like DAOPHOT [Stetson, 1987], has been very successful, and still is the “way-to-go” for single epoch photometry. However, differential photometry of highly crowded fields and therefore many blended sources can gain from the information gathered from the best resolving images, as will be explained in the following. Simply put, a best resolving reference frame is convolved by a kernel, which accounts for the PSF variation, to match each “epoch”-stack and then subtracted from them. The remainders show only sources with changing brightness.

4.3.1 Reference Frame

We build common deep reference frames for every DG field following the recipe of Sect. 4.2.10 for the “epoch”-stacks but with additional constraints: Only the best $\sim 10\%$ of the frames, i.e. with the highest weights, are used. Additionally a limit for the FWHM is applied to ensure that a reference frame PSF FWHM is not bigger than any of the individual “epoch”-stacks¹². Also, frames with saturated cosmics which are still masked “dominant” and occasional badly pointed epochs are dropped not to diminish the field-of-view. The reference frames will also provide the base for absolute photometry and colour-magnitude-diagrams later on as well as for the colour images and finding charts in Chap. 5 and App. G (Fig. 5.1, 5.6, 5.8, 5.14 - 5.17, 5.20 - 5.22, and G.3 - G.6).

⁹Which, again, is dominated by the photon noise of the skylight background.

¹⁰Even if considering bright sources where we are interested even in “faint” variations.

¹¹Actually, OIS is only one way to implement difference image analysis [Ciardullo et al., 1990, DIA]. E.g. Tomaney and Crotts [1996] use Fourier convolution as a means to the same end.

¹²Because the successive convolution can not deconvolve!

4.3.2 Photometric Alignment

Our OIS implementation has shown to produce much better results when a photometric alignment of the epoch-stacks to the reference frames is applied beforehand and the convolution kernel normalised to unity (next Sect.). This is due to a partial degeneracy in fitting a 2D additive flat surface (skylight background) and determining the volume of the PSF-convolution kernel in one step which worsens with crowding. We therefore determine the fluxes of well defined, isolated, stable, and bright sources in every stack by Kron [1980] aperture photometry¹³. The median-clipped average ratio of those flux references between an “epoch”-stack and the reference frame supplies the appropriate calibration factor.

4.3.3 Convolution and Subtraction

OIS determines an optimal convolution kernel by decomposing it into a set of orthogonal basis functions and solving for the parameters which provide the least-squares difference of the convolved reference stack and the photometrically adjusted epoch-stacks. To account for PSF variations over the field-of-view the images are subdivided into regions of suitable size. Our latest implementation [Riffeser, 2006, Sect. 5.12.1] utilises three Gaussians of different widths multiplied with polynomials up to sixth order resulting in a 49 parameter kernel and three parameter flat surface. Unlike the Alard and Lupton [1998] OIS we support the least squares calculation by our propagated pixel errors. The results are further improved by masking variable sources detected later on¹⁴ as to ignore for the kernel calculation¹⁵ and repeating the procedure. We save both, the convolved reference frames as well as the resulting difference images.

4.4 Photometric Calibration

4.4.1 Relative Photometry – PSF-Photometry on Difference Images

We first extract the PSF of a suitable, isolated, and bright point source in all the convolved reference frames of every DG field as a preliminary photometric standard. An error weighted fit of these PSFs to every pixel in the according difference frames then yields a measure of the difference flux in units of the preliminary photometric standard¹⁶. This error weighted fit can be seen as a sort of error-weighted-convolution with the epoch’s PSF. This data reduction step also renormalises the propagated error by the reduced χ^2 of this “PSF-fitting convolution” which is necessary because of the correlated noise¹⁷ introduced mostly by the translation procedure

¹³We used the software package YODA [Drory, 2003] to perform the photometry.

¹⁴This includes all the sources of Tab. 4.4, i.e. also the high proper motion or parallactic sources of App. E.2.

¹⁵But not for the convolution!

¹⁶Even if any of those “standards” was variable, and most bright sources are variable, at least at the % level, it would not hamper the results because it is always the same reference frame which is being convolved.

¹⁷Correlated noise is always present when presumably independent pixel “errors” meet again in successive image transformation steps. While the absolute “level” of the errors is compromised by this correlation, the individual, naive propagated errors are still reasonable weights against each other for fits.

(Sect. 4.2.9) but also by OIS. The validity of this renormalisation will come up when checking the level of the cumulative variability mask of Sect. 4.6.1 in the “empty” (\approx constant) regions.

4.4.2 Absolute Photometry – Adopting Photometric Standards

Whenever possible the photometric calibration is conducted using HST data. (Leo A, Pegasus, GR 8, and Aquarius: Holtzman et al., 2006; for Leo A also: Schulte-Ladbeck et al., 2002). A DAOPHOT [Stetson, 1987] catalogue from our observations is positionally cross-correlated with a subsample from the HST catalogue consisting of stars with colours typical for G, K and M giants. The HST $V - I$ colours and V -band magnitudes are then translated into Cousins [Bessell, 1979] R -band magnitudes using the colour tables published by Thé et al. [1990]. The resulting zero-point (ZP) for our R -band catalogue was obtained using a linear fit of the DAOPHOT magnitudes against the converted HST R -band magnitudes. This transformation was performed independently for the WST and the CA dataset¹⁸. For EGB 0427+63 we had to do an on-site calibration with photometric standard observations. We correlated observations of Leo A, GR 8, and EGB 0427+63 on photometric nights at Calar Alto with observations of NGC 2264 at the same epoch utilising previous measurements of Flaccomio et al. [1999]. Leo A and GR 8 provide an additional check for the validity of the HST calibration scheme¹⁹. The two photometry schemes differ well below 0.1 mag on average which can be seen as a measure for our systematic photometry error. The details of the absolute photometric calibration build Chap. 3 of Snigula [2006].

4.4.3 Average magnitudes vs. magnitude averages

When listing magnitudes²⁰ for the variable stars detected (Chap. 5) we give²¹ their calibrated brightness as derived from the DG photometric reference image which are close to magnitudes of average fluxes because they are a stack of many randomly selected epochs²². Usually²³, average magnitudes are derived directly from the observed light curves. This can only be accomplished if the complete light curve is sampled with an acceptable S/N ratio which is clearly not the case for all of our faint, short-period variable stars (e.g. Fig. H.1 and H.2). Magnitudes derived by Fourier decomposition, despite building on phase binned averages, do not solve this problem.

¹⁸The good overall agreement of both sets can serve as a first indicator for the validity of this calibration approach [see Snigula, 2006, Fig. 3.2].

¹⁹As shown in Snigula [2006, Fig. 3.4].

²⁰“**MAGNITUDE**, n. Size. Magnitude being purely relative, nothing is large and nothing small. If everything in the universe were increased in bulk one thousand diameters nothing would be any larger than it was before, but if one thing remain unchanged all the others would be larger than they had been. To an understanding familiar with the relativity of magnitude and distance the spaces and masses of the astronomer would be no more impressive than those of the microscopist. [...]” [Bierce, 1906]

While the advantage of a unit free of scale is obvious its potential drawback is not, see App. E.3.

²¹Unless explicitly stating differently.

²²This holds at least for periods up to ~ 200 days with the *VarStarDwarves* sampling. See Snigula [2006, Sect. 4.3].

²³In literature.

They even tend to be brighter than those from flux averages of the reference frame²⁴. To check on this deficiency I made the approximation that the light curve of Cepheid stars can be described by a sawtooth shaped function. I read the maximum magnitude $m_{\max(t=0)}$ from the diagrams of a couple of observed light curves and took the according flux averaged magnitudes $m_{\bar{f}}$ from the DAOPHOT catalogues of the reference frames. The missing minimum magnitude $m_{\min(t=1)}$ can now be calculated from the known $a = m_{\max(t=0)}$ and $m_{\bar{f}}$ by solving

$$\bar{f} = \int_0^1 10^{-0.4(a+t(b-a))} dt \quad (4.3)$$

for $b = m_{\min(t=1)}$ and

$$\bar{m} = \int_0^1 a + t(b-a) dt = \frac{b+a}{2} . \quad (4.4)$$

I found that average flux magnitudes tend to be a few 0.01 mag brighter than magnitude averages. But, this effect is always much less than 0.1 mag for typical Cepheid amplitudes.

4.5 Time Calibration

With the typical stacked exposure time being four times longer than the maximum light travel delay time barycentric effects should be negligible. Nevertheless, I proved the validity of that assumption by comparing Lomb runs (Sect. 4.6.2) on uncorrected and barycentric corrected data sets applying the algorithms of Meeus [1988] as implemented by the *skycalc* program of J. Thorstensen.

4.6 Variable Sources Detection

4.6.1 Preselection – A Cumulative Mask

To find VS candidates and to extract their light curves from the reduced data, we first build a mask frame where we count how often individual difference frames deviate from zero by at least 1σ , utilising the complete per-pixel error propagation of our data reduction pipeline.

This mask still contains information on the noise of the images as well as on the VS candidates which we intend to extract: The $(\kappa\sigma)$ clipped median of the cumulative mask corresponds to the number of 1σ outliers, where no variability is present, i.e. ≈ 32 of 100 epochs. The clipped standard deviation of the mask gives the noise of the 1σ -no-variability level. We select as variable star candidates all positions where the level of the mask exceeds its median value by 2 times the noise²⁵ and, in addition, DAOPHOT photometry of the reference image yielded a detected source within a radius of 1.5 pixels (Tab. 4.4, Col. 1). Then, using these coordinates as input, values and associated errors are read from the PSF-convolved difference images and the light curve data are assembled.

²⁴I.e. by 0.025 mag on average.

²⁵Selecting only positions which exceed this level by 2 times its noise yields a false detection probability for a single pixel of $\approx 5\%$ assuming a normal distribution.

4.6.2 Periodic Sources

The Lomb Algorithm

To search for periodic signals in the extracted difference fluxes we applied the Lomb [1976] algorithm using the interpretation from Scargle [1982] because a discrete Fourier Transform does not work for unevenly sampled data²⁶. The power spectrum $P(\omega)$ of the quantity X_j sampled at times t_j , i.e. the Lomb periodogram, is calculated by

$$P_X(\omega) = \frac{1}{2} \left\{ \frac{\left[\sum_j X_j \cos \omega(t_j - \tau) \right]^2}{\sum_j \cos^2 \omega(t_j - \tau)} + \frac{\left[\sum_j X_j \sin \omega(t_j - \tau) \right]^2}{\sum_j \sin^2 \omega(t_j - \tau)} \right\}, \text{ with} \quad (4.5)$$

$$\tan(2\omega\tau) = \left(\sum_j \sin 2\omega t_j \right) / \left(\sum_j \cos 2\omega t_j \right). \quad (4.6)$$

The arbitrary power density can be interpreted as a significance for a peak at frequency n among N test frequencies according to

$$p(\max_n P(\omega_n)) = 1 - [1 - \exp(-P(\omega_n))]^N \quad (4.7)$$

which contains a *statistical penalty* for the number of test frequencies²⁷.

Specifically, to find periodic variable stars in our observations I test a logarithmic grid of 23040 periods in the range from 45 minutes (our shortest stacked exposure time) to 1536 days. All sources yielding at least once a Lomb significance ≤ 0.25 were further examined. This limiting p -value was empirically chosen according to the test case of Leo A. It should be strictly enough to get rid of the most unbelievable light curves (clearly variable, but without any convincing period), but still weak enough to at least show up all variables with already known periods, even if the light curve would finally be manually discarded for being too unconvincing to contribute to a period luminosity relation.

The Lomb algorithm is sensitive to all sorts of periodic sources²⁸ It prefers sinusoidal light curves²⁹, but is not restricted to that curve shape and can deal even with very noisy data, good sampling provided. The only drawback of the algorithm is its susceptibility to window functions. This again can be minimised by clever sampling [Saunders et al., 2006], but of course only as far as nature allows. Ground based observations (restricted to one observing site) will always

²⁶Even resampling only works for a well sampled grid but for the bulk of the data we have just sparse sampling.

²⁷The more frequencies are tested the higher the probability of a random high power peak gets.

²⁸All kinds of pulsating variable stars, but also eclipsing binaries and, in combination with light curves derived from photometry at fixed coordinates, even to parallaxes, see also Sect. 4.2.9 and 4.3.

²⁹See Sect. 4.6.3 and App. D.

fight the imprinted signal of the day³⁰, month and year³¹ cycles, i.e. the Lomb power spectrum can be fooled by their window functions. All observing periods (1 d and 1 yr) and their integer fractions as well as non-observing periods (sidereal and/or synodic month, 1 yr) and their integer multiples can lead to artificial power.

Therefore, finding the real period of a VS can get quite complicated because its true period can be superimposed by a window function resulting in “resonance” power in an overtone mode of either the window or the true period or even their beat period. Visual inspection of the light curves always clearly favoured the period of a “smooth” curve, but that did not always be the one with the smallest p -value, i.e. the highest power.

To get rid of the most obvious window functions I disregarded all periods of $1\text{ d} \pm 1\%$, $1/2\text{ d} \pm 1\%$, and $1/4\text{ d} \pm 1\%$, because I had no way of distinguishing real from fake periods. I excluded ambiguous detections by selecting only the most significant Lomb candidate per DAOPHOT match.

The Lafler-Kinman Algorithm

While the Lomb algorithm has shown to be the superior method to detect periods of less than half a year in all of our samples it often gave indistinct solutions for the longer periods. Therefore, Snigula [2006, Sect. 4.2] applied the Lafler and Kinman [1965] algorithm to search for LPVs / Mirae stars. It proved to be less sensitive to the window functions caused by the yearly visibility gaps of our DGs.

4.6.3 Completeness Tests

Completeness tests were performed applying the techniques described in detail in Snigula [2006, Chap. 5]. Since new reference images had been created since, the artificial stars simulation (see below) and the DAOPHOT completeness had to be repeated.

Artificial stars simulation

To build artificial light curves first one or several grids³² of ≈ 1000 test stars in total with adapted flux and PSF are put into each stacked image of an epoch. This is done for the interesting range of magnitudes (16 mag to 26 mag, 0.1 mag stepping). Then the OIS and PSF-photometry

³⁰“**DAY**, n. A period of twenty-four hours, mostly misspent. This period is divided into two parts, the day proper and the night, or day improper – the former devoted to sins of business, the latter consecrated to the other sort. These two kinds of social activity overlap.” [Bierce, 1906] Astronomers manage to employ the former for the latter and vice versa thereby extending the overlap to identity, and rendering this artificial distinction between night and day completely obsolete.

³¹“**YEAR**, n. A period of three hundred and sixty-five disappointments.” [Bierce, 1906] In contrast to the above-quoted *cynical year* the *sidereal year* lasts 365 d, 6 h, 9 min, and 9 s (at the epoch J2000.0).

³²Depending on the apparent size of the dwarf galaxy: The grid may not be too dense to avoid crowding of the artificial sources. The distance of the artificial stars should be large enough that their convolution kernels would not overlap. If one grid with ≈ 1000 stars would have been larger than the host galaxy, we did several grids with offsets.

is applied according to Sect. 4.3 and 4.4. Tables giving flux and errors for every test star, epoch and test magnitude are extracted.

Variation mask completeness

Variation mask completeness was checked as detailed in Snigula [2006, Sect. 5.2.2]. The results show that the variation mask has no limiting impact on the recovery of artificial variable sources when compared to either DAOPHOT or Lomb completeness. [See Snigula, 2006, Tab. 5.1, 5.3, 5.5, and 5.7, and top Fig. 5.1, 5.3, 5.5, and 5.7.]

Lomb completeness tests

We tested two sets of light curves, cosine and sawtooth. The former is the easiest for a Lomb algorithm to detect, the latter is more or less the worst case³³. For the cosine we tested 0.2, 0.6, 1.0, and 1.4 peak-to-peak amplitudes, for the sawtooth, after a first test run, only 0.6, 1.0, and 1.4 (see below, Caveats). All tests cover a magnitude range of 18.0 to 25.0 (0.1 mag steps) and a period range of 0.15 to 129.95 days therefore including the whole range of periods known for Cepheids.

The results of the tests are displayed in Tab. 4.1, Fig. 4.1, showing the cumulative Lomb completeness for Leo A, and the figures of App. D, showing the cumulative Lomb completeness for the rest of our DGs as well as exemplary period resolved Lomb completeness again for Leo A. They can be summarised as follows:

- Completeness is dependent on light curve shape, average magnitude, and amplitude as expected.
- Completeness is nearly independent of the period, but for a slight drop at the shortest periods and around either the sidereal and the synodic month³⁴.
- No artificial increase in completeness could be seen at the obvious window function periods. Nevertheless any variability still can cause resonance power at the window functions frequencies.

Caveats

The completeness tests can only answer the question asked which is: *What is the probability of an arbitrary star with given average magnitude, amplitude, and period to result in a significant p-value for dwarf galaxy X for the actually observed epochs?* Since the p-value is empirically

³³A pure cosine will put all its power into a single fundamental Lomb mode, while a sawtooth will spread power also into many overtones. Cepheid light curves are somewhere in between those extremes.

³⁴Since observations with the target within less than 30° from the moon are drowned in moonlight, and therefore are avoided, as are observations during full moon in general, objects with those lunation periods will lose completeness earlier for the phases coinciding a maximum in their light curve and the objects “lunatic” blackout. Since EGB 0427+63 has the largest distance to the ecliptic it also shows the smallest impact due to lunation.

chosen according to the test case of Leo A (see Sect. 4.6.2), the test will only account for stars showing up in the automatically selected sample because of enough power in the Lomb spectrum at its true period. It will not give additional insights about the credibility of its light curve. It will also not tell if the input period would have been the one with most power in the resulting spectrum. And of course the test will not say if the power leading to a “significant” detection is “real” or due to window functions.

The Lomb completeness tests are very time consuming³⁵. We therefore had to compromise on the test grid density at various instances:

- Since the magnitude stepping is 0.1 mag the smallest amplitudes detectable are 0.2 mag for cosine light curves. Sawtooth light curves with 0.2 mag amplitudes have 50% of their points at average brightness and 50% of their points equally distributed above and below average which is still consistent with noise, i.e. non-periodicity.
- To bring down calculation time to a tolerable amount only a small region around the input period is tested ($P \pm 5\%$). Therefore the tests give no additional information on the influence of window functions at other than the tested period. Since the p -value also depends on the total number of tested periods it had to be renormalised to resemble the original Lomb periodogram setup for the variable sources search (Sect. 4.6.2).
- The flux of the artificial stars can dominate the OIS convolution which will lead to losing completeness at the “bright” side of the test mostly for small amplitudes and/or sawtooth light curves (e.g. see Fig. 4.1). This is due to the fact that the artificial stars grid has a common magnitude when put into the image yielding an “magnitude instance”. The details depend on the convolution grid size, the test star density, and the ratio of test star flux to real objects flux.
- We did not test for periods which are obvious window functions.

DAOPHOT completeness

DAOPHOT completeness tests yield limiting magnitudes for the photometric reference frames (Sect. 4.3.1). Snigula [2006, Sect. 5.2.3] details the parameters and recipe for obtaining those tests. Since Snigula [2006] new reference frames for the Pegasus dwarf and EGB 0427+63 had been obtained and therefore new DAOPHOT completeness tests had to be performed. Tab. 4.2 summarises the results, while Fig. 4.1 and Fig. D.1 to D.4 in App. D display the impact on overall completeness in combination with the Lomb completeness.

Adopted limiting magnitudes

We finally adopted the combined 50% completeness (Lomb \times DAOPHOT) of the 1.4 mag peak-to-peak amplitude cosine as an uniform limiting magnitude. All fainter sources were disregarded (Tab. 4.4, Col. 2).

³⁵The tests for all of the objects took more than 4 months on a 16 node 1.2 GHz Beowulf cluster.

Table 4.1: Period averaged results from the exhaustive Lomb completeness tests. Columns 1 and 2: Light curve test shape and peak-to-peak amplitude [mag]. Other columns: Magnitude of percentile completeness limit, i.e. percentage of Lomb significance $p \leq 0.25$ light curve recovery, and its standard deviation over the test periods. Boldface: 50% completeness columns and 1.4 mag peak-to-peak amplitude cosine light curve rows.

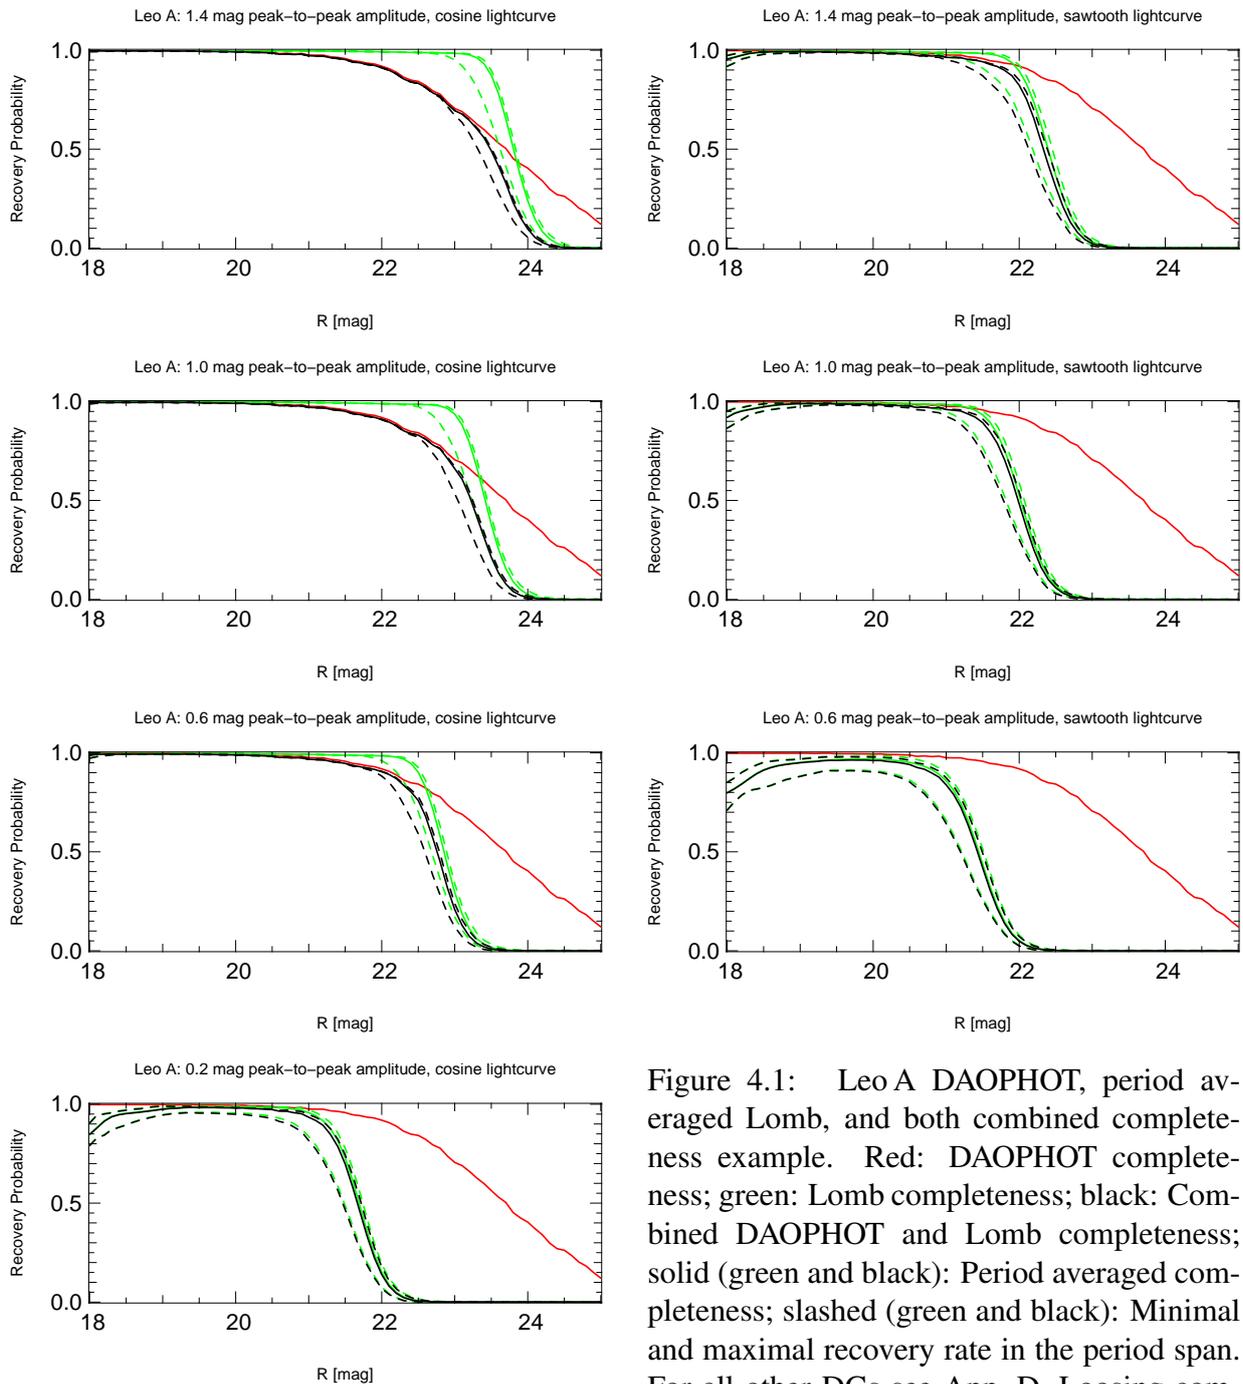

Figure 4.1: Leo A DAOPHOT, period averaged Lomb, and both combined completeness example. Red: DAOPHOT completeness; green: Lomb completeness; black: Combined DAOPHOT and Lomb completeness; solid (green and black): Period averaged completeness; slashed (green and black): Minimal and maximal recovery rate in the period span. For all other DGs see App. D. Loosing completeness on the bright end is due to intrinsic of the test (see text).

Table 4.2: DAOPHOT photometry completeness of the WST *R*-band reference images following Snigula [2006, Sect. 5.2.3]. In accordance with having the highest number of usable single epochs EGB 0427+63 also produced the deepest reference frame.

	99%	95%	90%	50%	10%	5%	1%
Leo A	20.4	21.6	22.1	23.7	25.0	25.0	25.0
Pegasus	20.5	21.8	22.2	23.8	25.0	25.2	25.6
EGB 0427+63	19.5	22.6	23.4	24.7	25.5	25.8	26.0
GR 8	20.8	22.2	22.7	24.2	25.3	25.5	25.9
Aquarius	18.9	21.7	22.5	23.6	24.4	24.7	25.0

Table 4.3: Combined completeness of DAOPHOT photometry on the *R*-band reference images (Tab. 4.2) and the Lomb simulations on the complete data sets (Tab. 4.1). (See also Fig. 4.1 and all figures of App. D.) Combined 50% completeness was adopted as limiting magnitudes for variable sources to be considered. Despite having the deepest reference frame EGB 0427+63 achieved the worst combined completeness limit. This is due to the significantly inferior single epoch stacks (worst average PSF) for this dwarf and probably caused by a problem with the mirror mount of the 80 cm telescope at “northern”, $> 60^\circ$ declinations.

	99%	95%	90%	50%	10%	5%	1%
Leo A	20.0	21.5	22.1	23.5	24.0	24.1	24.3

Aquarius	18.9	21.4	22.0	22.7	23.1	23.2	23.4

4.7 Variable Sources Classification

From here on, I will focus the discussion of data reduction on the major aim of finding classical and Type II Cepheid variables and establishing their periods and magnitudes:

After applying the limiting magnitudes I disregarded all candidates with periods of more than 130 days of the remaining, presumed periodic, variable sources. This upper limit reflects the longest periods known for δ Cephei stars in the Local Group [Groenewegen et al., 2004].

Table 4.4: Breakdown of variable sources detection: Variation mask $> 2\sigma$ and DAOPHOT match within 1.5 pixel radius, (mask threshold and total number of input epochs,) Lomb significance $p \leq 0.25$ corrected for DAOPHOT ambiguities and ignoring 1, 1/2, and 1/4 d periods, period limit $P \leq 130$ d and $m \leq$ limit according to Tab. 4.3.

	mask (thresh./total) > 2σ of 1σ var. lvl.	Lomb $p \leq 0.25$	$P(< 130$ d) + m limits
Leo A	12656 (47/120)	309	131
Pegasus	11290 (41/94)	525	214
EGB 0427+63	6754 (66/158)	326	40
GR 8	3445 (45/102)	65	16
Aquarius	6573 (39/85)	130	17

In order to quantify a classification scheme, in particular to identify δ Cephei stars, I tested two approaches on Leo A candidates. Firstly, I did a crude template fitting utilising a “typical” real δ Cephei star and adjusting only its magnitude, amplitude and phase shift by adaptive simulated annealing [Ingber, 1993]. The ratio of the fit’s r.m.s. and the r.m.s. of a constant curve should yield a means of picking up the most appropriate candidates. Secondly, I applied a four-mode Fourier decomposition using an error weighted Levenberg-Marquardt algorithm [Levenberg, 1944, Marquardt, 1963] to determine the usual mode amplitude ratios and phase differences ($R_{21}, \phi_{21}, \phi_{31}$, see e.g. Simon and Lee 1981), which obey certain rules for different kinds of pulsating variables. Because the S/N ratio of the light curves is too low for most but the brightest stars both methods failed to be conclusive.

Therefore, I finally applied a classification strategy based on a visual inspection of the light curve solutions for every candidate. I distinguished 3 groups of variable sources based on their period: Short periods $P < 1$ d, intermediate periods $1 \text{ d} < P < 10$ d, and long periods $10 \text{ d} \leq P \leq 130$ d (Tab. 4.5). The first group produced mainly light curves either indistinguishable from the remaining short period window functions³⁶ or with no regular light curve shape. Nevertheless, a few of those candidates had second power peaks yielding believable light curves at longer periods and were therefore added with their longer periods to the according group³⁷. The latter two groups were further divided into three subgroups each which reflect the significance of the detection (p -value). Again, second power peaks with believable light curves at different periods were added to the according group and subgroup.

³⁶1/3 d, 2/3 d, and 1/ N d ($N \geq 5$)

³⁷Numbers in brackets in Tab. 4.5.

Table 4.5: Variable sources candidates classification: Classification due to period P and significance p (additions because of convincing second power peaks in brackets in the order short, intermediate, and long period first power peak).

Period signif. p	$P < 1$ d	1 d $< P < 10$ d			10 d $\leq P \leq 130$ d		
	all	$< 10^{-4}$	$< 10^{-2}$	< 0.25	$< 10^{-4}$	$< 10^{-2}$	< 0.25
Leo A	61	9 (0, 2, 0)	8 (1, 3, 0)	39 (3, 1, 1)	2	2 (2, 0, 0)	10 (1, 1, 0)

Chapter 5

Results

The *VarStarDwarves* “Blues”¹

Preliminary results of the *VarStarDwarves* project have been published in Snigula et al. [2004, 2006] and Gössl et al. [2006]. The results on Long Period Variable, “red” stars were detailed in Snigula [2006], while the results on shorter period variable, “blue” stars will be reported on here. In App. E, I report about “by-chance” discoveries and missing objects which were beyond the scope of the *VarStarDwarves* project but for some reason caught the eye of the observer: Sometimes they caused problems with difference imaging like high proper motion and parallactic stars (App. E.2) or small solar system bodies (App. E.1, Tab. E.1). Other objects were interesting because of their physics and their potential as distance indicators like Supernovae (App. E.3).

5.1 Some History – Dwarf Tales

5.1.1 Leo A

The LG dIrr galaxy Leo A (DDO 069, Leo III, UGC 05364)² was first mentioned by Zwicky [1942]³. It had been discovered in a survey with the 18” Schmidt telescope on Palomar Mountain.

¹Twinkle, twinkle little star, How I wonder what you are. . .

²Naming in astronomy is as confusing as can be. In particular, for faint galaxies and/or LG galaxies there exist several schemes: Arbitrary naming by its or after the discoverer(s), after constellation with additional consecutive Roman numerals (modern use only for dSphs) or capital letters (originally for galaxy clusters and now befitting dIrrs), simply by a catalogue number with the catalogue usually named after the observatory which carried out the underlying survey (DDO = David Dunlop Observatory Catalogue of Low Surface Brightness Galaxies, van den Bergh [1959, 1966]; UGC = Uppsala General Catalog of Galaxies, Nilson [1973]; UGCA = Uppsala General Catalog Appendix, Nilson [1974]). I will give here the most common names under which the *VarStarDwarves* objects are known among astronomers.

³Mistaking it for a galaxy cluster.

The first distance⁴ guess was given by de Vaucouleurs [1975] to $m - M \approx 25.2$ mag. Jacoby and Lesser [1981] derived an upper limit for its distance from an associated Planetary Nebula (PN) $m - M < 27.5 \pm 0.5$ mag. Sandage and Tammann [1982] first gave a distance from the brightest red stars to $m - M = 27.4 \pm 0.3$ mag; Demers et al. [1984] estimated its distance from the brightest blue stars⁵ to $m - M = 26.8 \pm 0.4$ mag whereas Sandage [1986] gave, also solely based on the brightest blue stars⁶, a distance modulus of $m - M = 26 \pm 1$ mag. Hoessel et al. [1994] derived a first distance based on what they thought were δ Cephei variable stars of $m - M = 26.74 \pm 0.22$ mag confirming the previous estimates. Meanwhile Skillman et al. [1989] had determined the Leo A metallicity as one of the lowest known in the local universe. They derived an oxygen abundance of $12 + \log(\text{O}/\text{H}) = 7.30 \pm 0.05 (\approx 2.4\% \text{ solar})$ from a PN in Leo A, a result which was confirmed by van Zee et al. [2006] who additionally measured the oxygen abundance of four H II regions to $12 + \log(\text{O}/\text{H}) = 7.38 \pm 0.10$.

Hubble Space Telescope (HST) observations were needed to call into doubt the Hoessel et al. [1994] Cepheid distance: Tolstoy et al. [1998] derived a distance modulus of $m - M = 24.2 \pm 0.2$ mag from various features in the HST colour-magnitude diagram (CMD)⁷. Their modelling of the CMD suggests a metallicity as low as $Z = 0.0004$ which is consistent with the oxygen abundance measurements. They also claim that Leo A is predominantly young and an underlying old population cannot contribute more than 10% to the total star formation. This was rejected by Schulte-Ladbeck et al. [2002]⁸ in the sense that Leo A is mainly young only in its centre but has overall an underlying intermediate and even an old population (up to 50% older than 10 Gyr). Thinking of an old population leads them to give $m - M = 24.5 \pm 0.2$ mag from the *I*-band TRGB and the position of the so called red clump (RC) in the HST CMD. Their proposed star formation history is also strongly supported by our findings of 11 *VarStarDwarves* LPVs [Snigula et al., 2006, Snigula, 2006].

Finally, Dolphin et al. [2002] discovered eight RR Lyrae stars in Leo A and derived from them $m - M = 24.51 \pm 0.12$ mag. This result is also confirmed by our preliminary analysis of three *VarStarDwarves* Leo A δ Cephei stars [Gössl et al., 2006]; they fit a Madore and Freedman [1991] PLR with $m - M = 24.47 \pm 0.10 \pm 0.06_{ZP}$ mag.

⁴“**DISTANCE**, n. The only thing that the rich are willing for the poor to call theirs, and keep.” [Bierce, 1906] Many observing astronomers prefer to give distances d not in units of parsecs [pc] but as a distance modulus $m - M = 5 \log(d/10 \text{ pc})$, especially when derived from the brightness of “standard candles”.

⁵They did not find any bright red stars.

⁶He still found bright red stars but now those gave a degenerate solution for distance determination. Sandage emphasised that “*the distance is determined poorly by this method*”.

⁷A CMD is the modern observer’s equivalent to the HRD. A single waveband’s brightness measurement in mag accounts for the luminosity while the colour, i.e. the difference of two wavebands in mag and therefore actually a flux ratio, indicates the temperature.

⁸Again utilising HST observations but this time with some offset from the galaxy centre.

5.1.2 Pegasus Dwarf

The Pegasus Dwarf or Peg DIG (DDO 216, UGC 12613) was discovered in the early 1950s by A.G. Wilson during his work for the Palomar Observatory Sky Survey (POSS)⁹ and first referenced by Holmberg [1958]. It shows almost the same early history as Leo A: The first guess by de Vaucouleurs [1975] here was $m - M = 21.2$ mag while the Jacoby and Lesser [1981] PN upper limit yielded $m - M < 29.0 \pm 0.4$ mag. The Sandage and Tammann [1982] red supergiant distance here was $m - M = 28.19 \pm 0.3$ mag. Hoessel and Mould [1982] from a sparsely sampled TRGB and brightest red and blue stars deduced $m - M = 26.1 \pm 0.3$ mag. In contrast, Sandage [1986], after a very thorough discussion, derived only a very vague $25 < m - M < 29 \pm 1$ from brightest red and blue stars. Hoessel et al. [1990], again, were still far off with their presumed δ Cephei distance of $m - M = 26.22 \pm 0.20$ mag; Aparicio [1994] challenged the Hoessel et al. distance as he derived $m - M = 24.9 \pm 0.1$ mag from an *I*-band TRGB. While Gallagher et al. [1998] concluded an $m - M = 24.4 \pm 0.2$ mag distance modulus, mostly because they adopted a 0.3 mag higher *I*-band extinction, McConnachie et al. [2005] confirm his result; they give a $m - M = 24.82 \pm 0.07$ mag TRGB distance modulus. Our preliminary δ Cephei distance, $m - M = 24.92 \pm 0.2 \pm 0.06_{ZP}$ [Gössl et al., 2006], is also consistent with those findings.

Aparicio and Gallart [1995], Aparicio et al. [1997] derived a significant old population with oldest stars ≈ 15 Gyrs, several bursts of star formation in recent epochs, and a metallicity as low as $Z = 0.002$ whereas Gallagher et al. [1998] concluded an even lower metallicity of $Z = 0.001$ and most stars forming about 2 – 4 Gyrs ago¹⁰. Our findings of 52 LPVs [Snigula et al., 2006, Snigula, 2006] is best explained by the latter star formation history.

5.1.3 EGB 0427+63

EGB 04 27 +63 (UGCA 092) was found by Ellis, Grayson, and Bond [1984] while looking for faint Planetary Nebulae in the POSS. A first CCD photometry by Hoessel et al. [1988] did only yield a lower limit for the distance $m - M > 24.5$ mag. Karachentsev et al. [1997] derived $m - M = 26.25$ mag from the brightest blue stars. It was not until Karachentsev et al. [2006] that its distance was more firmly established from HST data by means of the TRGB method to $m - M = 27.39 \pm 0.18$ mag.

5.1.4 GR 8

GR 8 (DDO 155, UGC 08091) was discovered by G. Reaves [1956] while looking for dwarf galaxy candidates within the Virgo galaxy cluster. Early distance estimates range from 22.5 mag $< m - M < 27.6$ mag [Hodge, 1967, brightest blue stars]. Hodge [1974] gave a variety of distance estimates: They mostly narrowed down the upper limit derived from H II regions to $m - M < 27.0$ mag and gave an average distance of 1 ± 0.5 Mpc⁴. (de Vaucouleurs and Moss [1983] interpreted his results as a median distance of $m - M = 25.5 \pm 0.5$ mag.) de Vaucouleurs [1978]

⁹The POSS was conducted with a 48" Schmidt telescope in two photographic bands and is still the largest survey in optical wave bands.

¹⁰But they find stellar ages up to ~ 8 Gyrs compatible with their data.

also from brightest blue stars and the diameter of H II regions derived $m - M = 25.0 \pm 0.3$ mag. de Vaucouleurs and Moss [1983] got $m - M = 25.25 \pm 0.4$ mag from brightest red and blue stars¹¹, total magnitude, H II, and H I measurements whereas Hoessel and Danielson [1983] found $m - M = 26.1$ mag from carbon stars but combined this result with Hodge [1974] to derive $m - M = 25.6 \pm 0.8$ mag. Aparicio et al. [1988] obtained $m - M \approx 25.0$, again from bright blue stars, but points out that this distance modulus “*still remains poorly determined*” because of a huge error due to statistical effects as explained by Schild and Maeder [1983] and Greggio [1986]. Skillman et al. [1988] determined the oxygen abundance of GR 8 to be $\sim 3\%$ solar which is confirmed by modern measurements of $\sim 5\%$ solar [van Zee et al., 2006].

Finally, Tolstoy et al. [1995] found a single Cepheid in GR 8 and derived from it a distance modulus of $m - M = 26.75 \pm 0.35$ mag which we recovered in our preliminary results [Gössl et al., 2006, $m - M = 26.45 \pm 0.07 \pm 0.06_{\text{ZP}}(\pm 0.25_{\text{PLR}})$]. Dohm-Palmer et al. [1998] find this distance consistent with their TRGB estimate from HST CMDs.

5.1.5 Aquarius Dwarf

The Aquarius Dwarf (DDO 210) was first reported on in the DDO survey [van den Bergh, 1959, 1966]. Its LG membership has been based on similarities with other members and an inbound galactocentric velocity [Fisher and Tully, 1975]. Marconi et al. [1990], Greggio et al. [1993] first still considered a $m - M \approx 25$ mag but later conclude that their best fitting model to a CMD has $m - M \approx 28$. Lee et al. [1999] procured $m - M = 24.89 \pm 0.11$ mag from an *I*-band TRGB. McConnachie et al. [2005, 2006] more or less confirm this result by their *I*-band TRGB distance modulus of $m - M = 25.15 \pm 0.08$ mag. However, our *VarStarDwarves* survey failed to detect any LPV in the Aquarius Dwarf [Snigula, 2006] which remains a puzzle if this distance is correct.

5.2 *VarStarDwarves* Data

The observations of Tab. 2.3 did yield 119 (41) Leo A, 78 (0) Pegasus, 158 (45) EGB 0427+63, 102 (49) GR 8, and 85 (10) Aquarius WST (CA) *R*-band epochs suitable for the “Lomb” detection (the consistency check). LGS 3 had only 48 epochs at the end of 2005 and therefore its analysis was deferred until enough data become available. The parameters of the 418 *VarStarDwarves* candidates (Tab. 4.5) will only partly be displayed in the next sections; the longest and/or least relevant tables, finding charts, and additional light curves are shown in App. F, G, and H, respectively.

5.2.1 Leo A – The Test Case

An overview of the VS candidates for Leo A is displayed in the CMD of Fig. 5.2. There is one big caveat¹² to start with: While the *R*-band magnitudes and their errors are reliable the *B*–*R* colours

¹¹In Moss and de Vaucouleurs [1986] they exclude the formerly brightest blue star as a galactic foreground contaminant but do not change their distance estimate.

¹²It applies generally for all subsequent CMDs presented here, i.e. Fig. 5.9, 5.16, and fig. 5.18.

Figure 5.1: Colour composite image of Leo A: Red channel = CA *I*-band reference image, green channel = WST + CA *R*-band reference images, blue channel = CA *B*-band reference image; exponential scaling.

and their errors are not. The according reference frames going into the DAOPHOT photometry combine different epochs for the two filters¹³ and therefore the colour should be only interpreted as a hint; the actual colour may be off by almost an amplitude of the VS¹⁴ and the errors for the colours are combined DAOPHOT photometry errors which are known to be a lower limit at best. The CMD background (grey squares) shows the typical features of a young population (upper main sequence and blue loops region, i.e. the “*blue plume*”, left centre/top) mixed with an intermediate and maybe old population (RGB, AGB; bulk of data and right top). To allow for a

¹³Only 3 epochs for *B*-band CA and the “blue” amplitude is larger than the red one!

¹⁴LM01 (see below) definitely has this sort of systematic error in colour. The probable location of the instability strip is not at $B - R \approx 1.0$ mag as hinted by the “right” green circles but more at $B - R \approx 0.7$ which is the “green” average colour.

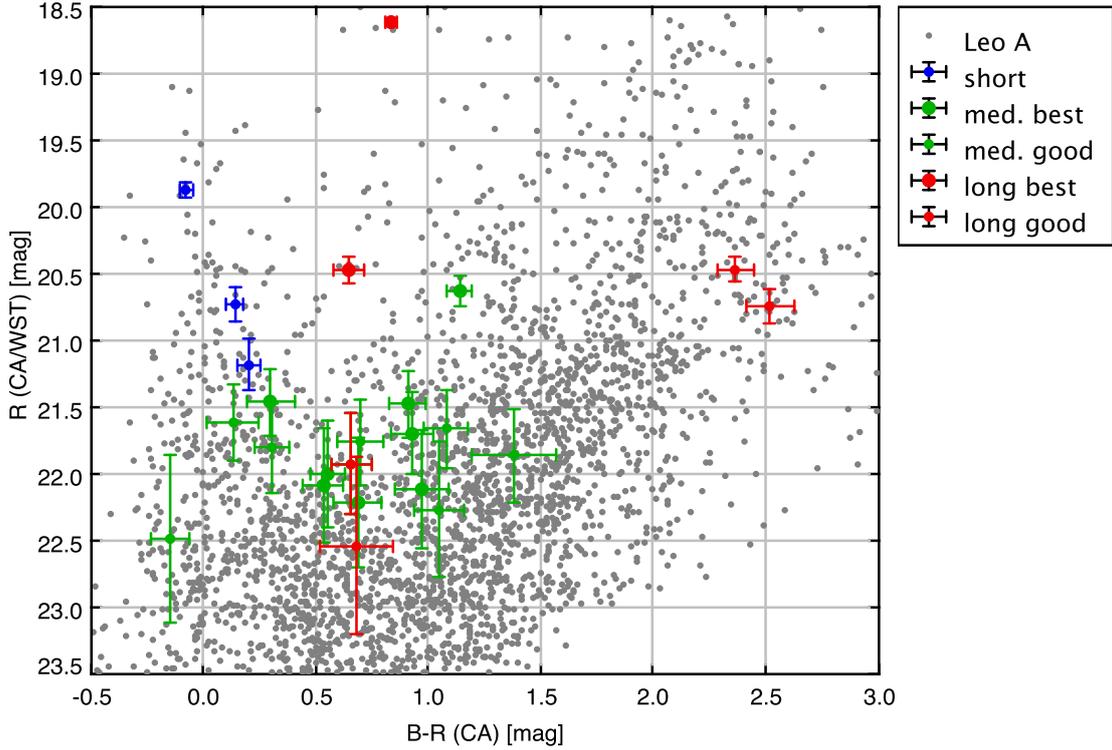

Figure 5.2: Leo A CMD – grey: CA R -band (uncorrected) vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998, $A_R = 0.055$, $A_B = 0.89$); other colours (VS candidates): WST R -band (uncorrected) and propagated errors vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998) and DAOPHOT errors (see caveat in text!); blue: $P < 1$ d, $p < 0.25$, Tab. F.1; green: $1 \text{ d} < P < 10 \text{ d}$, $p < 0.01$, Tab. 5.1; red: $P > 10 \text{ d}$, $p < 0.01$, Tab. 5.2 top. See Fig. G.1 for a CMD indicating all VS candidates.

more easy cross identification of the VS candidates in the successive figures and tables only the $B - R$ colour has been corrected for galactic foreground extinction [Schlegel et al., 1998] but not the R -band brightness.

The photometry and Lomb results of all longer period ($P > 10 \text{ d}$) candidates and the best and good medium period ($1 \text{ d} < P < 10 \text{ d}$, $p < 0.01$) will be shown here (Tab. 5.2 and 5.1), the worse medium period ($0.25 > p > 0.01$) and all short ones ($P < 1 \text{ d}$) follow in App. F (Tab. F.2 and F.1). Fig. 5.6 is a “special” finding chart for the Leo A candidates discussed here; finding charts displaying all VS candidates grouped by period ranges can be found in App. G.

At least eight, maybe ten, of the LS candidates are due to the diffraction spikes of a bright star in the field¹⁵ (LS9, LS11, LS23, LS34, LS36, LS45, LS51, and LS55, and probably also LS 31 and LS59; Tab. F.1). Some candidates are also probable blends, i.e. they have close location and period (LM40 & LM49 of LM 15, LM50 of LM26, LS39 of LS25; Tab. F.2, 5.1, and F.1).

¹⁵Caused by the secondary mirror mount. Unfortunately, there is no compact, reflective off-axis (free of obstruction) telescope design available so far.

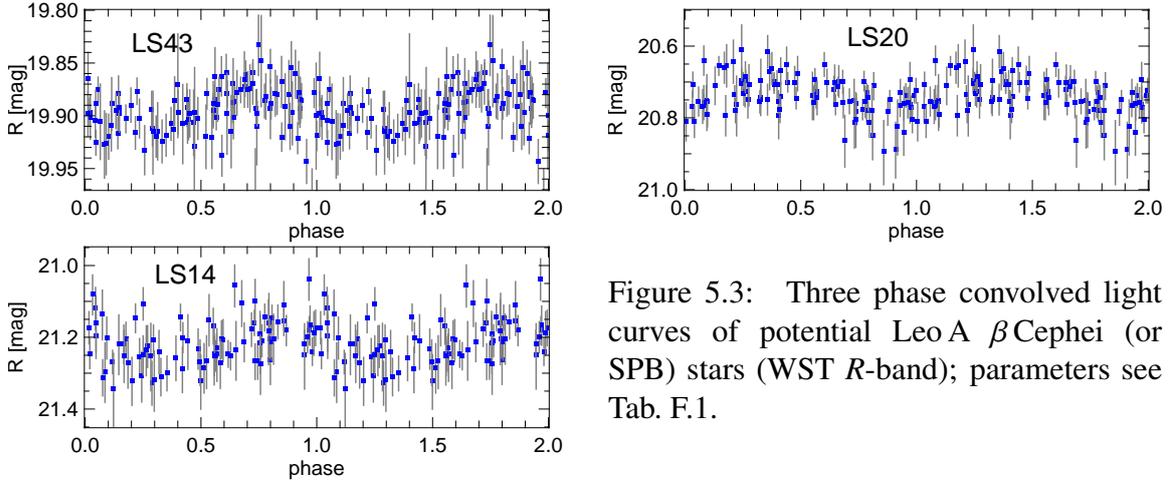

Figure 5.3: Three phase convolved light curves of potential Leo A β Cephei (or SPB) stars (WST R-band); parameters see Tab. F.1.

β Cephei (or SPB) Candidates

Of the three bluest and brightest VS candidates within the “blue plume” which contains the main sequence (Fig. 5.2, blue, $B-R < 0.25$, $R < 21.5$; LS43, LS20, and LS14¹⁶ of Tab. F.1; Fig 5.6 blue LS) at least the brightest one (LS43) shows a promising light curve (Fig. 5.3) and may actually be a β Cephei (or SPB) star. This comes as a surprise as one would not expect to find any β Cephei in hosts with the very low Leo A metallicity. The brightest candidate is certainly adequate ($R = 19.88$ mag) to try a direct metallicity determination with a 10 m-class telescope and is definitely worthy of further investigation¹⁷. All other short period VS are either too faint (noisy light curve) or too “red” (or both) to be considered here. Some of the bluest Cepheid candidates, discussed in the next paragraph, might also be added here, especially those which display multi-periodic behaviour. LM09, LM16, and LM17 with respective short periods of $P = 0.39$, 1.86, and 0.74 d are the most prominent to mention here. LM02, despite a tempting “Cepheid” colour, has also a convincing alternate period of $P = 0.72$ d and, like all the former, lies with its longer period clearly above a Leo A δ Cephei PLR. If any of this multitude of candidates could be confirmed either the metallicity assessment of Leo A or the pulsation theory for B-stars would have to be revised. Disproved candidates still might be Eclipsing Binaries which would also allow for interesting science from follow-up observations (Sect. 1.5.5).

“Cepheids” with periods $1 \text{ d} < P < 10 \text{ d}$

Tab. 5.1 top and Fig. 5.4¹⁸ show the most promising δ Cephei candidates. The Lomb detection is based solely on the WST data (blue squares), the CA data (red circles) serves only as a consistency check. LM01 and LM03 are so far the longest period δ Cephei stars known in Leo A.

¹⁶With periods $P = 0.095$, 0.184, and 0.822 d respectively.

¹⁷Considering that the period of LS43 is smaller than three times the typical exposure stack time span of ~ 45 minutes the signal is thus smoothed, but still large. However, to confirm LS43 photometrically 7 hours straight with a series of ~ 10 minute exposure at a 1.5 m class telescope should suffice.

¹⁸See Fig. H.1 for the $0.0001 < p < 0.01$ candidates light curves of Tab. 5.1.

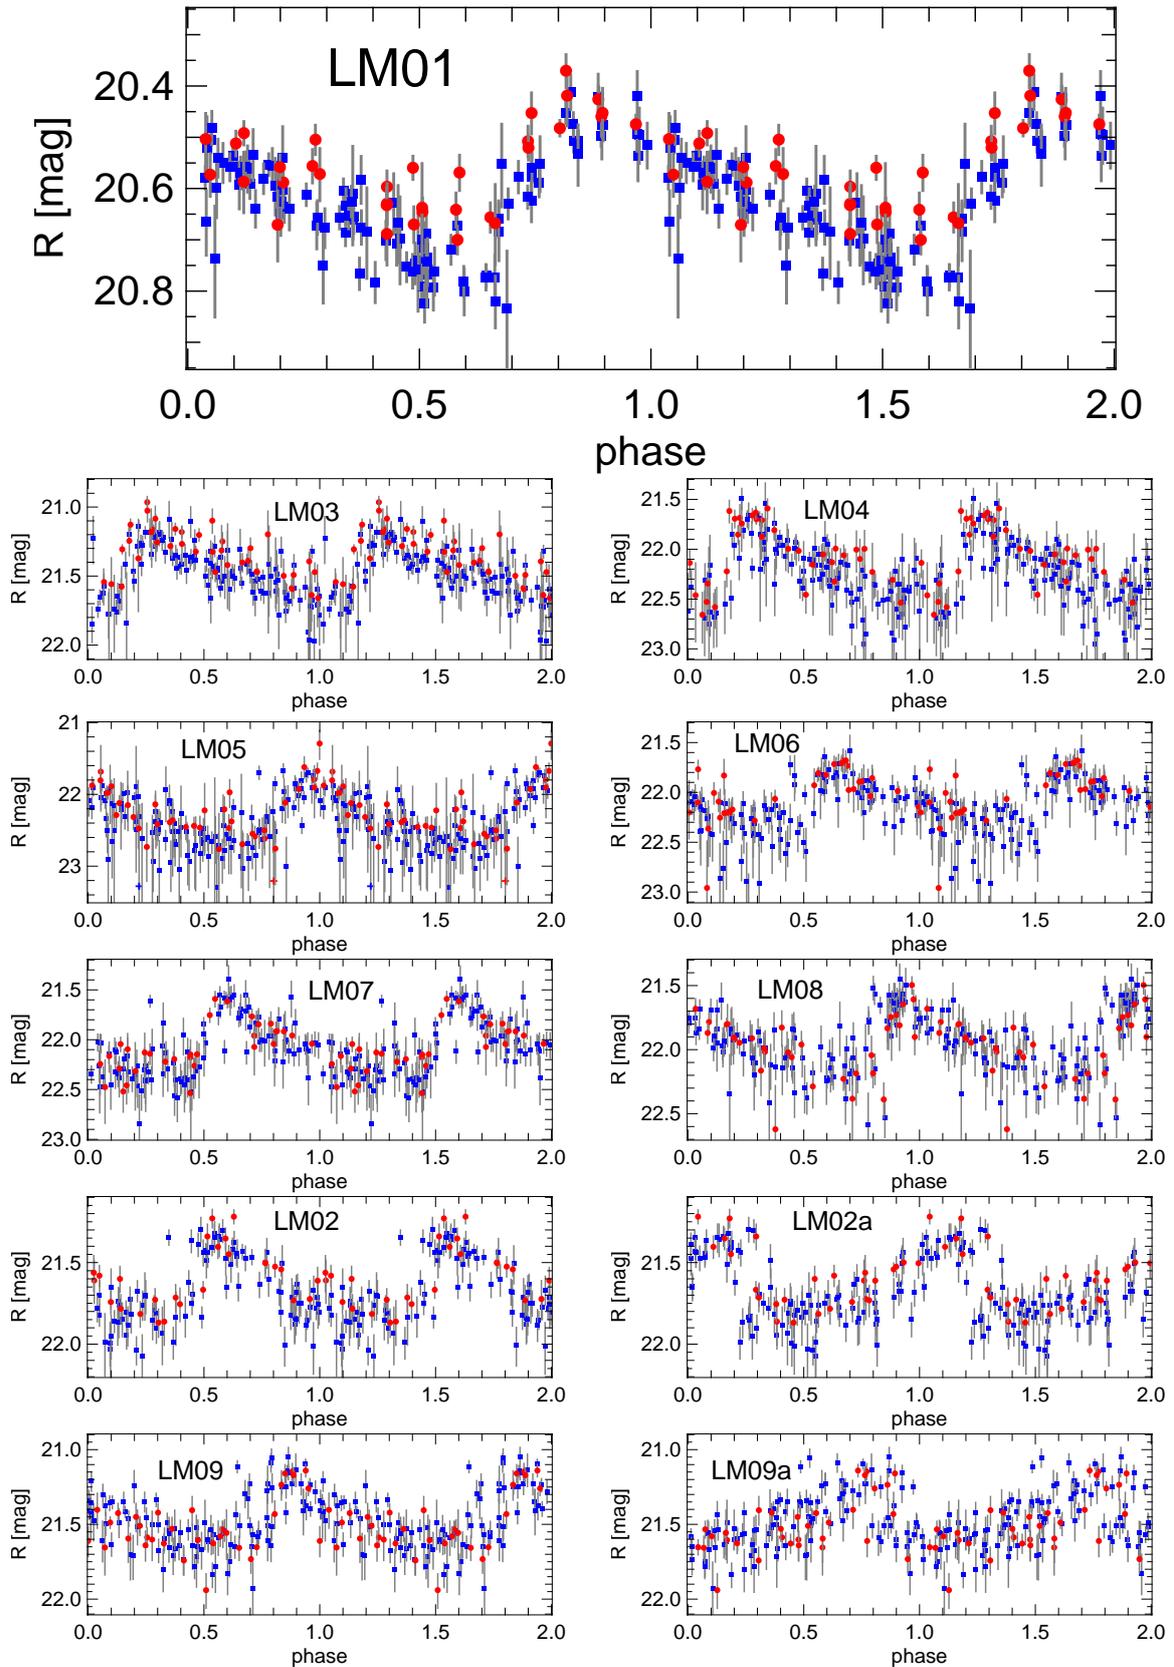

Figure 5.4: Leo A best ($p < 0.0001$, period $1\text{d} < P < 10\text{d}$) δ Cephei candidates phase convolved light curves. Blue squares: WST data (Lomb detection); red circles: CA data (consistency check); coloured crosses: Data consistent with detection limit at epoch, i.e. $S/N < 1$ at either site; grey: 1σ errors. For additional ($0.0001 < p < 0.01$) light curves see Fig. H.1.

Table 5.1: Parameters of Leo A best and good Cepheid $1 \text{ d} < P < 10 \text{ d}$ period candidates: Short identifier (see Fig. 5.6), IAU compliant identifier, position, most significant Lomb period(s), significance (p -level), flux averaged apparent R -band magnitude, r.m.s. error of R -band magnitude.

In some light curves the CA data are systematically brighter or fainter than the WST data. This is due to the fewer CA reference epochs resulting in a reference image which provides worse magnitude averages than the WST ones (Sect. 4.4.3). Further discussion will follow below when reporting about PLRs.

“Cepheids” with periods $10 \text{ d} < P < 130 \text{ d}$

Only longer period VS candidates (Tab. 5.2) are bright enough¹⁹ to be considered as Type II Cepheids. LL01 displays a typical RV Tauri light curve (Fig. 5.5) whereas LL02 is already too noisy to decide on a designation. However, both light curves would display rather low amplitudes if they indeed were RV Tauri and would also be more on the “blue” side of the instability strip at least as far as the colours can be trusted²⁰ (Fig. 5.2, the 2 top left most red circles). LL03, LL06,

¹⁹Compare Tab. 4.3 with the PL diagrams in Fig. 5.7.

²⁰See caveat for colours but also Footnote 14 on the location of the instability strip.

LL11, LL13 and LM29*a* are in most respects similar to LL02 but show even less clear light curves; their colour, however, would be more indicative of Mirae²¹ stars (Fig. 5.2, red and yellow markers with $B - R \geq 2.0$). The periods of LL04, LL10, and LS16*a* are so close to lunation that they might be caused by the according window function. LS01*b*, LL05, LS02*a*, LL13, and LL14 are the most promising candidates besides LL01 and LL02 for Type II Cepheids in terms of light curve²² and colour. Further discussion, again, will follow in the PLR paragraph.

Literature cross-references

LM08 and LM04 might be identical to two of four VS candidates suggested by Sandage [1986, Fig. 5] but it is almost impossible to be sure from the poorly printed finding chart alone²³. Of the Hoessel et al. [1994, Tab. 3] VS candidates probably three, maybe four, match with some of our candidates²³ (Tab. 5.3). However, the *VarStarDwarves* photometry is systematically brighter and the periods do not agree at all. But, since none of the Hoessel et al. [1994] Cepheids could be confirmed later on and their PLR distance was way off this comes as no surprise.

²¹In the course of this thesis there will be no further classification, e.g. SRa stars will also be labelled Mirae.

²²See Fig. 5.5 for their light curves

²³There is no astrometric solution, not even some arbitrary coordinate system, given in the publication.

Table 5.3: This work’s VS candidates cross-correlated with Hoessel et al. [1994], Tab. 3; visual inspection of finding charts (? = doubtful identification, + = probable match).

21 of the 92 Dolphin et al. [2002] VS candidates are within 3.5" radius of *VarStarDwarves* ones²⁴ (Tab. 5.4). Ten of the 16 clear identifications with $\Delta < 1''$ have compatible period solutions ($|P_{VarStarDwarves} - P_{Dolphin}| \lesssim 1\sigma_{Dolphin}$). This is very remarkable: The Dolphin et al. [2002] results are based on observations in three consecutive nights with the WIYN 3.5 m on Kitt Peak yielding 23 half hour exposures in the V -band aiming at periods less than 2 days. This can be normalised to a total of about 140 hours 1 m aperture exposure. Our 119 half hour R -band exposures at the 0.8 m WST telescope have an equivalent of only 38 hours 1 m aperture exposure. While 0.7" seeing is typical for the WIYN observations the 0.8 m WST delivered $> 1.4''$ on average²⁵. Therefore, one would expect our data to have at best only 25% of the WIYN data S/N ratio, i.e. to be about 1.5 mag fainter. But, our image processing and data reduction scheme apparently can overcome those odds despite additionally only aiming at periods longer than 2 days with our observational setup. In case of the $P > 2$ d “matches” the WST period solution is definitely superior to the WIYN one because of the larger time line base. Candidates with $\Delta > 1''$ are probably mismatches, but for LM43 which may be actually a blend of C2-V28 and C2-V29. In case of LL14 and LS53 I consider the Dolphin et al. [2002] as the better solutions because of their deeper and more densely sampled data. The “true” WST period of LM47 is probably erased because we ignored 0.5 d detections as they are most probable due to a window function. For LM10 and LM53 the case is not settled yet and future observations will have to show which, if any, period solution will prevail.

Leo A VS finding chart

Comparing the distribution of shorter, medium, and longer period candidates over the field²⁶ shows that the medium periods (LM01-17) are concentrated in the star bursting core of Leo A

²⁴Dolphin et al. [2002] at least give CCD pixel coordinates which together with their finding charts and some pain I could translate into celestial coordinates.

²⁵No airmass correction!

²⁶See Fig. 5.6 for a “glimpse”, but better compare Fig. G.3, G.4, G.5, and Fig. 4.4 of Snigula [2006].

Table 5.4: This work’s VS candidates cross-correlated with Dolphin et al. [2002], Tab. 3, automated list within 3.5” radius. Match column: + = good period match; – = bad period match; d = bad distance (and period) match; b = period mismatch may be caused by variable blending; w = “true” *VarStarDwarves* period maybe lost in erased window function period; $\Sigma = 21$: 10+, 4–, 5(+1)d, 1 b, 1 w.

while the longer periods show a more diffuse distribution. This can be interpreted as tracing different populations, i.e. medium periods the younger populations in star forming regions and longer periods the older populations of the extended Leo A halo reported by Dolphin et al. [2002].

PLRs and the distance to Leo A

The excellent sample of the Fig. 5.4 δ Cephei candidates allows for the first time to derive a reliable PLR distance to Leo A: Fig. 5.7 shows the VS candidates of Tab. 5.1, F.2, and 5.2 in the context of a Madore and Freedman [1991] PLR (Eqn. (1.3)) shifted to the best fitting distance modulus of LM01, LM03, LM06, and LM08, i.e.

$$\text{Leo A } m - M = 24.48 \pm 0.10(\pm 0.06_{ZP}) \text{ mag.} \quad (5.1)$$

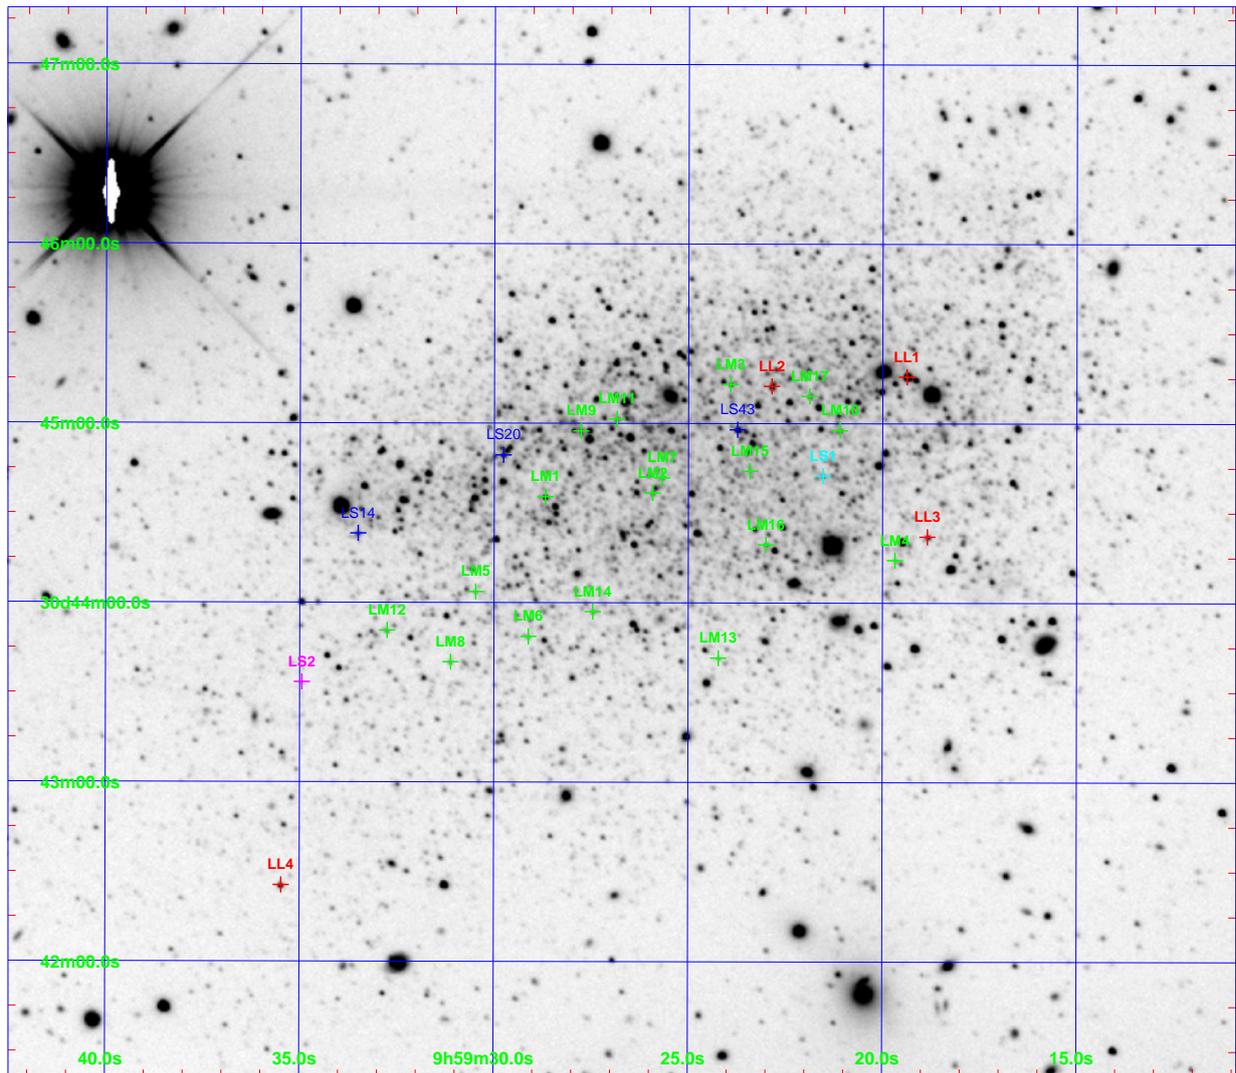

Figure 5.6: Finding chart of selected VS candidates, mostly of Tab. 5.1 and 5.2 but partly also from Tab. F.1. Blue: LS short period pulsating B-star candidates; green: LM most promising δ Cephei candidates; red: LL long period Type II Cepheid candidates. turquoise and purple: Candidates with interesting secondary period solutions.

This result is consistent with both the Schulte-Ladbeck et al. [2002] TRGB_r and the Dolphin et al. [2002] RR Lyrae distance. LM04 and LM05 still perfectly agree with this relation but were not included in the fit because Bauer et al. [1999] report a significant change in the slope of the SMC PLR for periods < 2 d. LM07 coincides with the according Caputo et al. [2004] First Overtone relation (Eqn. (1.2)). LM02 and LM09 (Fig. 5.7, blue diamonds) might either be so called “beat” Cepheids pulsating simultaneously in the Second and First Overtone or the Second Overtone and the Fundamental Mode respectively or SPB stars displaying multiple excited

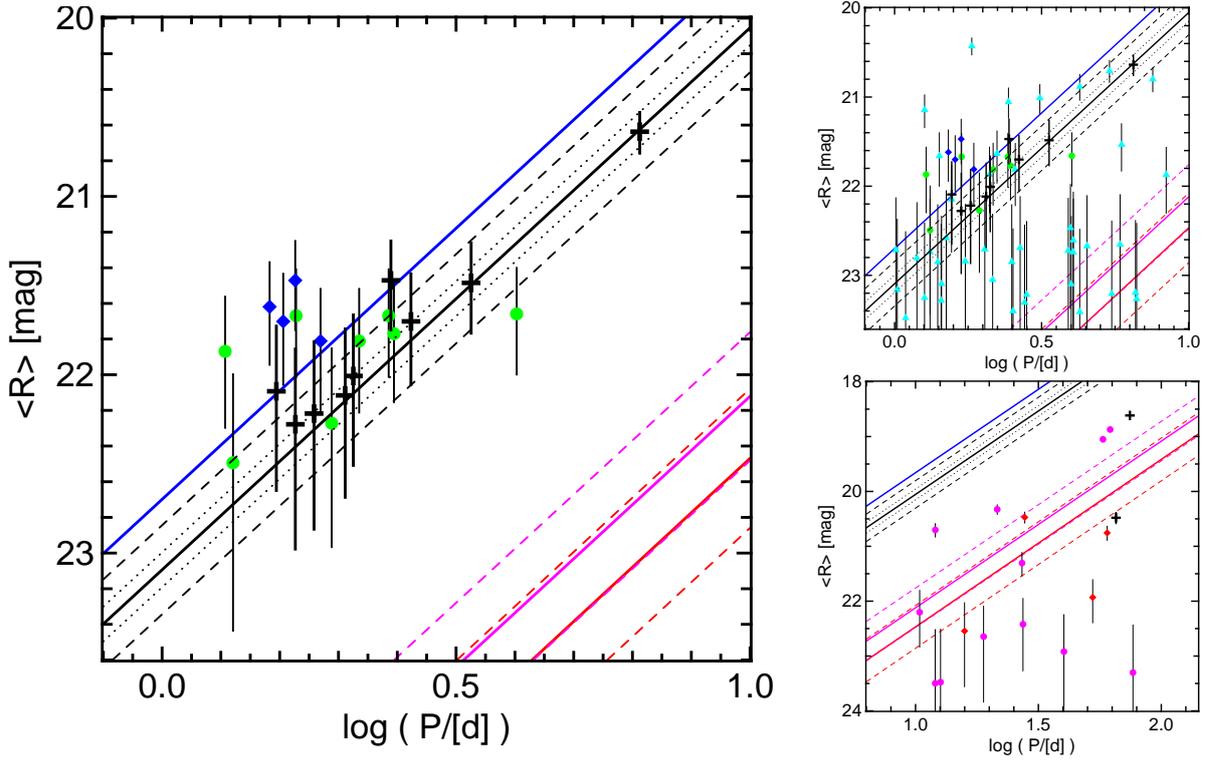

Figure 5.7: Solid black line: R -band period-luminosity relation for fundamental mode LMC Cepheids, Eqn. (1.3) [Madore and Freedman, 1991] corrected for galactic extinction [Schlegel et al., 1998, $A_R = 0.055$]. The PLR shown is best-fitting the observed Leo A δ Cephei stars average magnitudes $\langle R_f \rangle$ and periods of LM01, LM03, LM06, and LM08 (Tab 5.1). The fit is dominated by the longest period star LM01 due to its small error; it yields a distance modulus of $m - M = 24.48 \pm 0.10 (\pm 0.06_{ZP})$ mag including random errors and errors of the calibration. LM02 and LM09 were ignored because of their ambiguous period solutions (see text). Other candidates are either too short period ($P < 2$ d) or have less convincing Lomb significances ($p > 0.0001$) to be considered. Dotted black lines show the propagated error of the fit while dashed black lines indicate the error of the PL relation. Solid blue line: First Overtone relation according to Eqn. (1.5). Red and purple lines denote Type II PLRs and their errors (Sect. 1.5.4, Eqn. (1.4) and (1.5)). Black crosses: Highly significant ($p < 0.0001$) VS candidates; blue diamonds: Pulsating B-stars candidates; green circles: Less significant ($0.01 > p > 0.0001$) shorter period ($P < 10$ d) VS candidates; turquoise triangles: Low significant ($0.25 > p > 0.01$) shorter period ($P < 10$ d) VS candidates; red diamonds: Less significant ($0.01 > p > 0.0001$) longer period ($P > 10$ d) VS candidates; purple circles: Low significant ($0.25 > p > 0.01$) longer period ($P > 10$ d) VS candidates.

modes. The probability of a blend is $\sim 3\%^{27}$ within $21 \text{ mag} < R < 22 \text{ mag}$, therefore, the a priori probability that all of LM02, LM07, and LM09 are not enhanced by blending is $> 90\%$. The

²⁷I.e. the highest density of stars in the core of Leo A within the brightness range $21 \text{ mag} < R < 22 \text{ mag}$ per $2'' \times 2''$ cell.

bluer colour of LM02 together with the low probability of 2/1 beat Cepheids points more towards a SPB star while LM09 has a more suitable “Cepheid” colour; however, the highest significant period yields a typical Cepheid shaped light curve for both cases. Two other SPB candidates (LM16 and LM17) with “blue” colours are also indicated by blue diamonds in Fig. 5.7. Of the remaining $0.01 > p > 0.0001$ candidates (green circles in Fig. 5.7; light curves in Fig. H.1) the most convincing in terms of light curve is LM13 which also lies exactly on the derived PLR. Higher precision and multi-colour photometry with a very dedicated ZP calibration can reduce the PLR distance error but will be only worthwhile if the current tackling of PLR systematic errors concludes an improved solution.

The turquoise triangles Fig. 5.7 illustrate the more or less random distribution of successively less significant candidates. This has to be kept in mind when “grasping at straws” for some other DGs in the *VarStarDwarves* sample. They also show an aggregation of candidates at about 4 d due to an unforeseen window function.

Fig. 5.7 right, bottom shows all candidates with periods $10 \text{ d} < P < 120 \text{ d}$ relative to the Type II Cepheid PL relations derived in Sect. 1.5.4 (Eqn. (1.4) and (1.5)). Of the candidates remaining from the previous discussion (in terms of colour and light curve) LL02, LL05, LS02a, and LL14 are more or less compatible with the (red) PLR but show successively less convincing light curves. However, LL01²⁸ which is the most clear and interesting case would be too bright by at least one magnitude to be compatible with the (“bluer”, i.e. the purple) PLR. The probability for LL01 being a blend is even lower than for the previously discussed medium period candidates. But, Alcock et al. [1998] also see the trends of “brightening”, rather small amplitudes and “bluer” colours for the longer period RV Tauri in their MACHO data base²⁹. One can speculate that low metallicity might even enhance these trends. So far there are no theoretical models to compare with available. Nevertheless, LL01 is a very interesting star: It may well be both, the most metal poor and most distant, RV Tauri star known so far. And, it is within reach of spectroscopic observations which we intend to do.

Leo A, as a test case, shows the feasibility of our strategy: The overall data reduction scheme and the detection limits applied which are described in the previous Chap. 4 are “conservative” in the meaning of keeping even low significant periodic sources. While this helps identifying interesting objects with either quasi- or multi-periodic behaviour or near to our detection limit the sources to derive reliable PLR distances should be selected with caution, i.e. only those with a high Lomb significance suit³⁰. Another lesson learnt already here, but even more with the next galaxy candidate, the Pegasus Dwarf: Already a single “rough” colour helps a lot in identifying both, interesting special cases (e.g. pulsating B-stars) and possible contaminants (e.g. blends or other type of VS). And presumably: More and more precise colours would help even more, i.e. might even allow to disentangle to some degree atmospheric extinction, dust extinction and intrinsic temperature of the source. But, realistically speaking, this is still beyond the capability of our site and equipment.

²⁸And LL13 if one would be convinced by its light curve.

²⁹See also Fig. 1.4.

³⁰In our case at least $p < 0.01$ but better $p < 0.0001$.

Figure 5.8: Colour composite image of Peg DIG: Red channel = WST R -band reference image, green channel = WST $R+b$ -band reference images, blue channel = WST b -band reference image; exponential scaling.

5.2.2 Pegasus Dwarf – Settled

Our Pegasus Dwarf observations lack CA data and therefore neither include an independent check of the HST based calibration scheme [Snigula, 2006, Tab. 3.1]³¹ nor “standard” Johnson [1965] $B - R$ colours. The WST “blue” band observations were done with a very broad

³¹Therefore, no error estimate for the ZP can be derived, but one has reason to assume that it will not deviate much from the ZP error calculated for Leo A (0.06 mag).

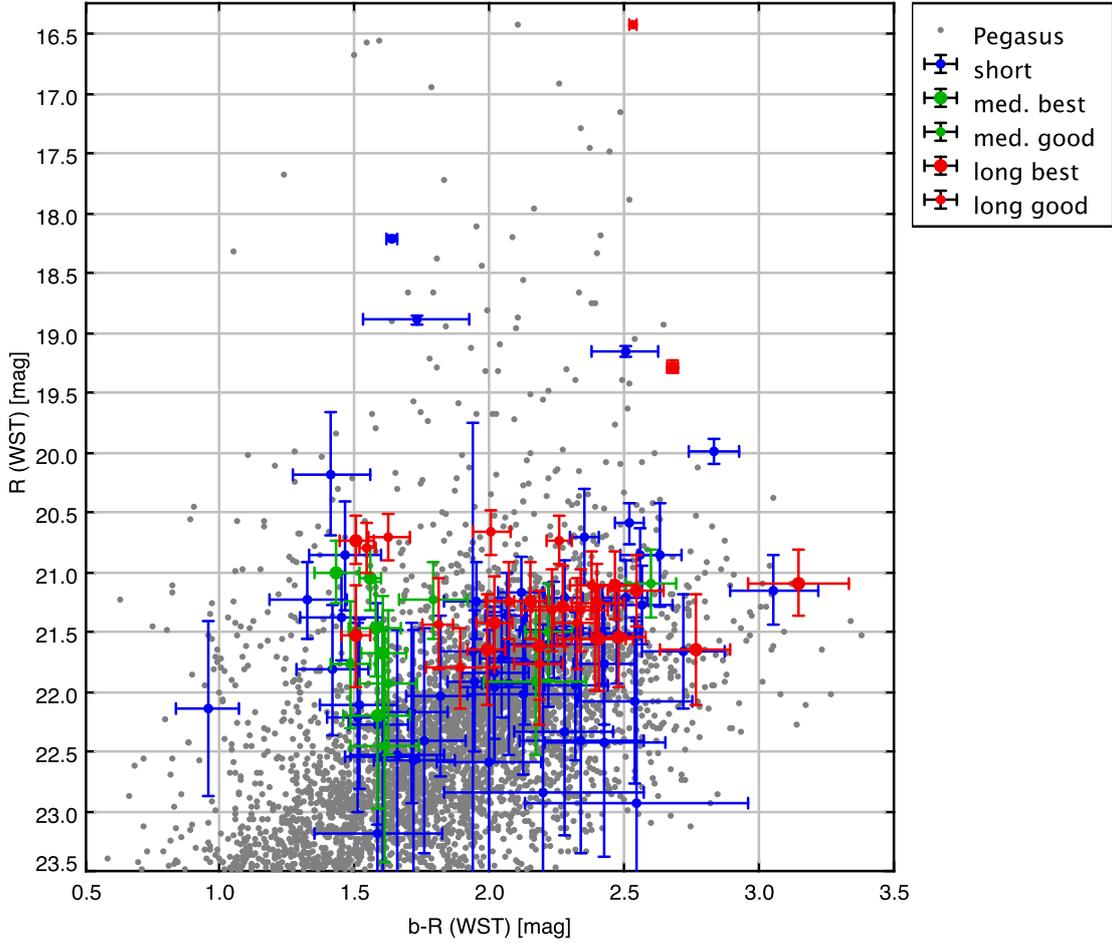

Figure 5.9: Pegasus Dwarf CMD – WST R -band (uncorrected) vs. WST $b - R$ colour (extinction correction after Schlegel et al., 1998, $A_R = 0.176$, $A_B = 0.284$); WST R -band propagated brightness errors, WST $b - R$ DAOPHOT colour errors. Please note the discussion of the WST b -band calibration and the derived colour in the text. Blue: $P < 1$ d, $p < 0.25$, Tab. F.3; green: 1 d $< P < 10$ d, $p < 0.01$, Tab. 5.5; red: $P > 10$ d, $p < 0.01$, Tab. 5.6. Fig. G.2 indicates all VS candidates.

BV -filter (Fig. 2.1) which introduces great uncertainties when translated to Johnson [1965] B without colour terms corrections³². Also, the zero-point relies on a single night which might have been not as photometric as presumed. Therefore, the $b - R$ colour in Fig. 5.9 should only be interpreted as an “instrumental”, relative quantity and actually is at least half a magnitude redder than expected³³. The CMD of Pegasus (Fig. 5.9) compared to that of Leo A (Fig. 5.2) shows a heavily populated RGB with an about 0.2 mag fainter tip, a blue (main) sequence, however, is hardly discernible. From these observations alone one would derive that Pegasus is slightly further away, has a much more massive intermediate (and maybe also old) population, and much less relatively recent star formation than Leo A.

³²Which, again, would require additional observations in other filter bands.

³³At least half of this huge colour offset would also be explained if the higher than Schlegel et al. [1998] extinction assumed by Gallagher et al. [1998] was correct.

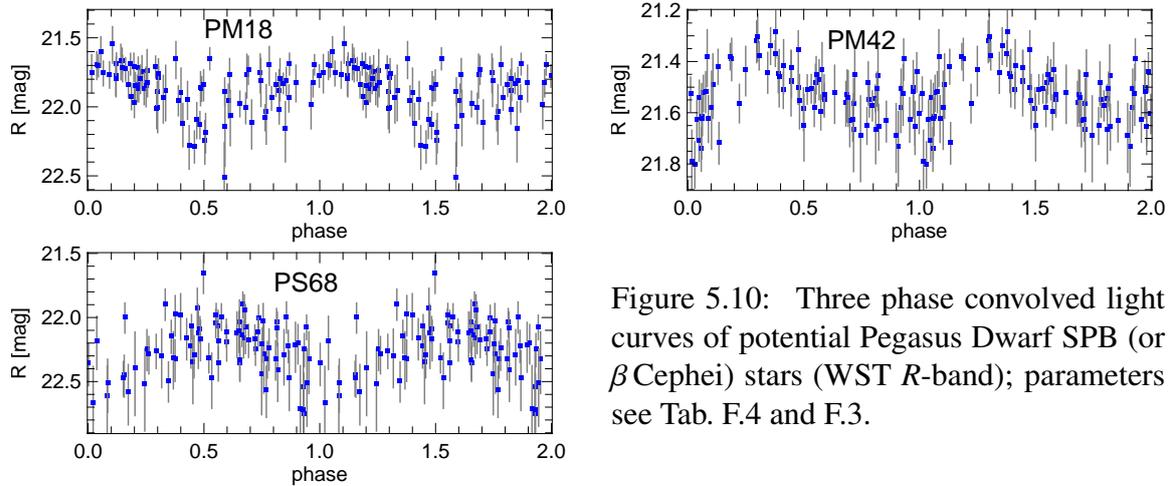

Figure 5.10: Three phase convolved light curves of potential Pegasus Dwarf SPB (or β Cephei) stars (WST R -band); parameters see Tab. F.4 and F.3.

At least 10 of the shorter period (PS) and 5 of the worse intermediate period (PM) candidates are due to diffraction spikes (see Fig. G.6 blue and turquoise). There is also some VS candidate blending which in some cases means that most probably only one candidate is “real” and the other only wrongly cross-correlated with the DAOPHOT source list. Most prominent here are PM02 and PM06 as well as PL01 and PL05; both pairs also show matching periods which also points at a DAOPHOT misidentification (see also Tab. 5.5, 5.6, and Fig. 5.14). Some VS candidates are clearly associated with unresolved background objects³⁴, but, being unresolved, no further information can be derived for either of them.

SPB (or β Cephei) candidates

The three “bluest” variable stars of Fig. 5.9 PM18, PM42, and PS68 (of Tab. F.4 and F.3, Fig. 5.14) have periods of 2.7, 3.7, and 0.87 days respectively which, together with their suitable brightness and convincing light curves (Fig. 5.10), would qualify them as SPB stars. But, while the metallicity of the Pegasus Dwarf is higher than that of Leo A (Sect. 5.1 and references therein) it is still too low to be consistent with those findings and the predictions of B-star pulsation theory. Unfortunately, the candidates are already too faint to allow for a spectroscopic metallicity determination.

Shorter period “Cepheid” candidates and a new classical δ Cephei PLR distance

Tab. 5.5 gives the parameters of all VS candidates with periods $1 \text{ d} < P < 10 \text{ d}$ and Lomb significance $p < 0.01$ while Fig. 5.11 displays only the candidates with clear and promising light curves. A first PL-diagram which showed also a Madore and Freedman [1991] PLR at a Schlegel et al. [1998] corrected McConnachie et al. [2005] distance temptingly identified several of the

³⁴PS25, PL54, PM44, and PM 58 are within a background spiral galaxy; PL54 might even be due to a AGN⁴² as it sits right on the galaxy core. PM37 and PL65 lie either within a massive Pegasus globular cluster or a background elliptical galaxy. (Again see Fig. G.6 for reference.)

Table 5.5: Parameters of Pegasus best and good δ Cephei $1 \text{ d} < P < 10 \text{ d}$ period candidates: Short identifier (see Fig. 5.14), IAU compliant identifier, position, most significant Lomb period(s), significance (p -level), flux averaged apparent R -band magnitude, r.m.s. error of R -band magnitude.

Tab. 5.5 candidates being consistent with the PLR or the according First Overtone relation but could not explain also many of the candidates which were off the relation. Therefore, I narrowed down the selection criteria to derive a subsample for distance determination not depending on previous knowledge, only selecting sources with a colour within the narrow band of the probable location of the instability strip, a clear light curve, and periods longer than 2 d.

This way following candidates were **not** considered for distance determination: PM03, despite showing a clear Cepheid like light curve, has the bluest colour of the Tab. 5.5 candidates; it is also too bright to be consistent with the finally derived PLR distance. One explanation might be that it actually is a Second Overtone Pulsator but since those are very rare it might more probably be blending with a blue star of similar brightness which also is at odds with statistics³⁵ but still “possible”. PM05 has an almost symmetric light curve which disqualifies it for selection despite its suitable colour. PM06 is most probably a blend of PM02 and also too red to be considered. PM07, PM10, PM12, and PM14 have periods of less than 2 d (PM10 and PM14 are probably still associated with the 1 d window function, PM10 is also too red in addition). Finally, PM09 and PM13 were dropped for red colours (PM13 also shows a very unclear light curve).

³⁵A similar estimate as in Sect. 5.2.1 yields a blending probability of less than 10% for PM03, i.e. the highest density of stars in the mag range of 21 to 22 is 0.087 per $2'' \times 2''$ cell. This is an upper limit as DAOPHOT does a better job at deblending as is assumed here.

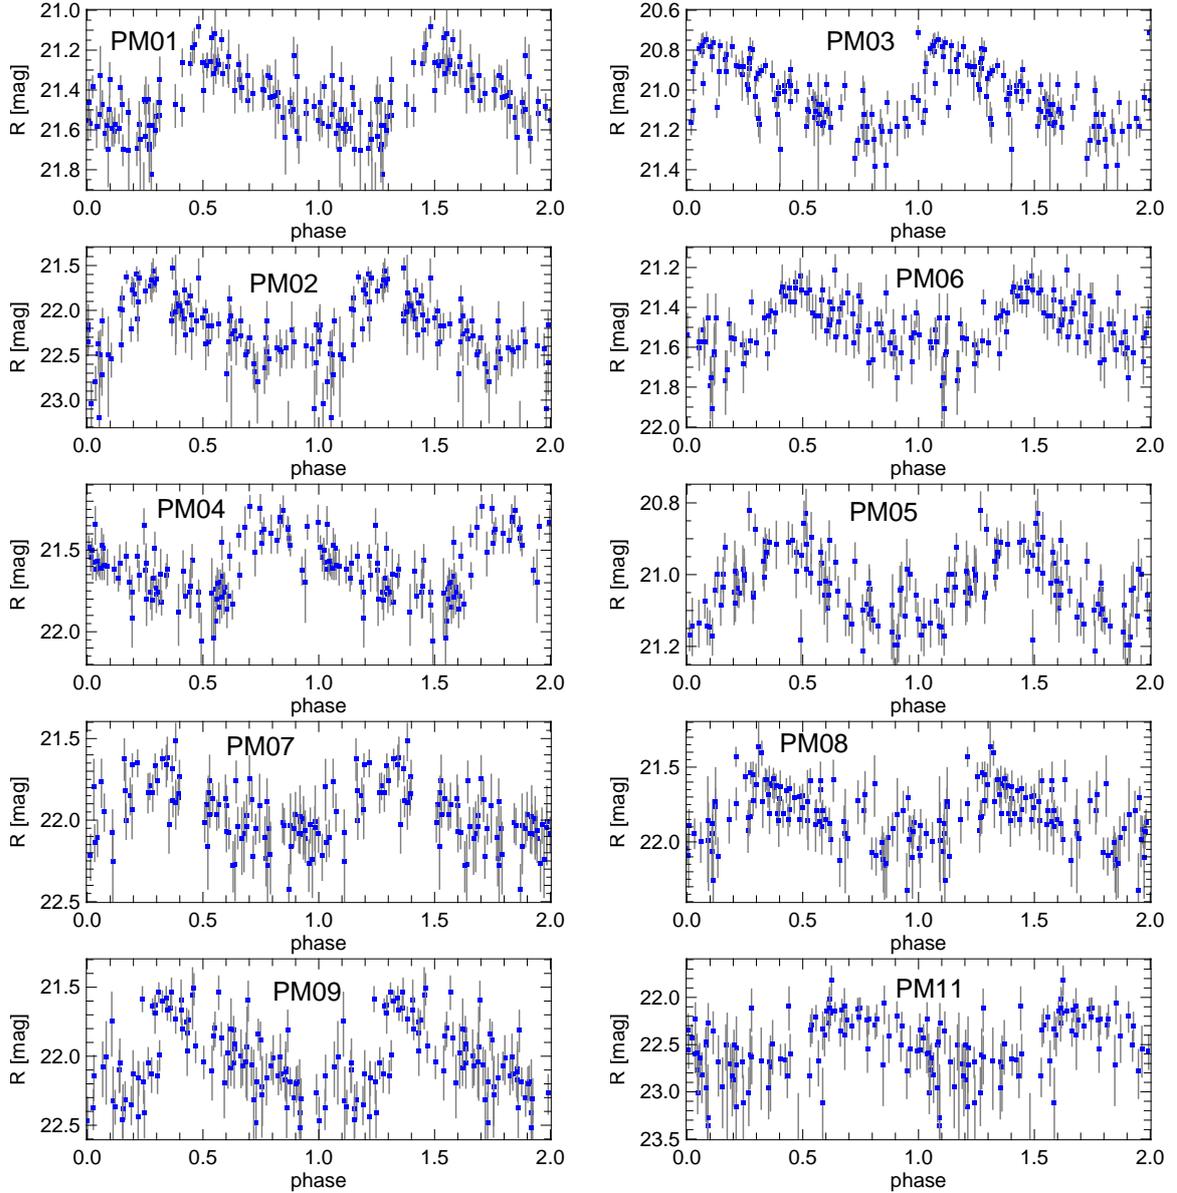

Figure 5.11: Pegasus Dwarf best δ Cephei candidates phase convolved light curves from Tab. 5.5. Blue squares: WST R -band data (Lomb detection). grey: 1σ errors.

This leaves PM01, PM02, PM04, PM08, and PM11 for distance determination. PM01 and PM08 I assume to be First Overtone Pulsators from their suitable brightness offset when compared with the other “distance” candidates and consider them with their according Fundamental period applying Eqn. (1.2). An error weighted fit of a Madore and Freedman [1991] R -band PLR including a Schlegel et al. [1998] extinction of $A_R = 0.176$ yields

$$\text{Pegasus } m - M = 24.72 \pm 0.24 \text{ mag} \quad (5.2)$$

which is perfectly consistent with previous TRGB distances (see references in Sect. 5.1). This

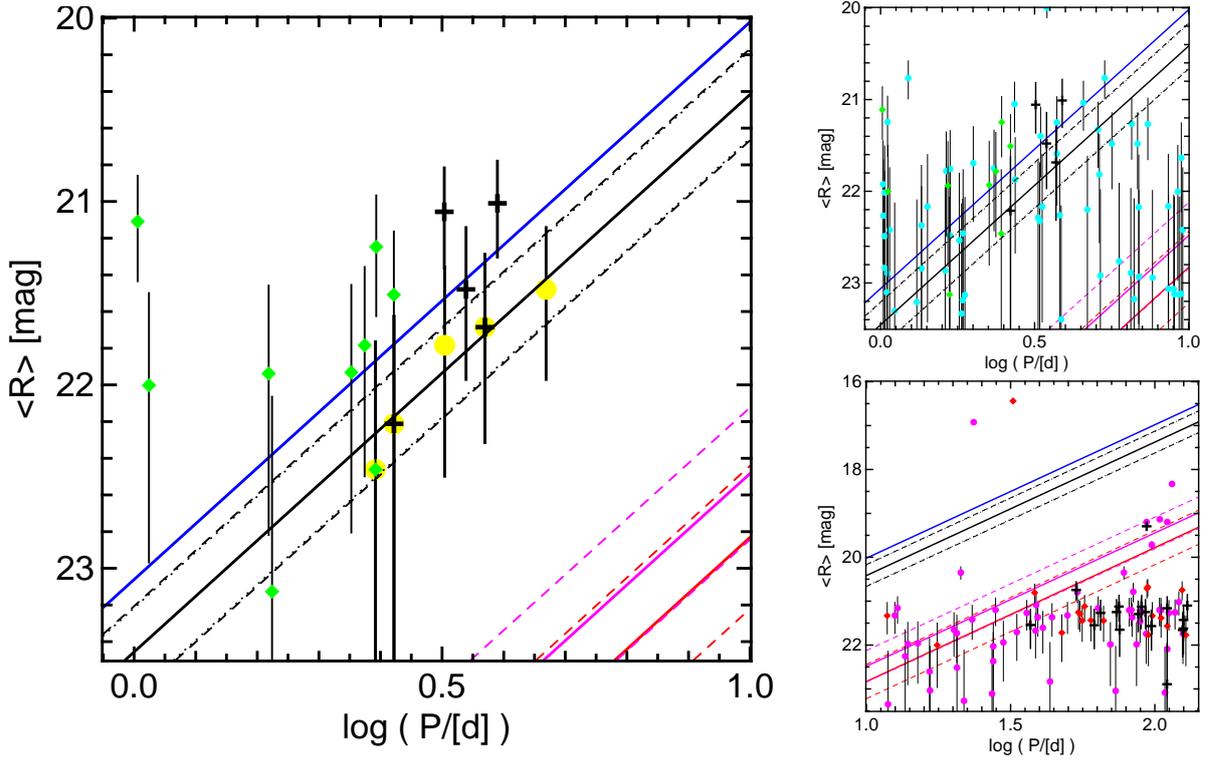

Figure 5.12: Solid black line: R -band period-luminosity relation for fundamental mode LMC Cepheids, Eqn. (1.3) [Madore and Freedman, 1991] corrected for galactic extinction [Schlegel et al., 1998, $A_R = 0.176$]. The PLR shown is best-fitting the observed Pegasus Dwarf δ Cephei stars average magnitudes $\langle R_f \rangle$ and periods of PM01 (FO), PM02, PM04, PM08 (FO), and PM11 (Tab. 5.5). The fit yields a distance modulus of $m - M = 24.72 \pm 0.24$ mag. See text on selection of the candidates contributing to the fit. Dotted black lines show the propagated error of the fit while dashed black lines indicate the error of the PL relation which happen to be almost identical. Solid blue line: First Overtone relation according to Eqn. (1.5). Red and purple lines denote Type II PLRs and their errors (Sect. 1.5.4, Eqn. (1.4) and (1.5)). Black crosses: Highly significant ($p < 0.0001$) VS candidates; green diamonds: Less significant ($0.01 > p > 0.0001$) shorter period ($P < 10$ d) VS candidates; clear yellow circles: Fundamental periods of presumably First Overtone δ Cephei candidates contributing to the PLR distance; underlying yellow circles (two under crosses, one under diamond): Fundamental mode δ Cephei candidates contributing to the PLR distance; turquoise circles: Low significant ($0.25 > p > 0.01$) shorter period ($P < 10$ d) VS candidates; red diamonds: Less significant ($0.01 > p > 0.0001$) longer period ($P > 10$ d) VS candidates; purple circles: Low significant ($0.25 > p > 0.01$) longer period ($P > 10$ d) VS candidates.

result can still be greatly improved by a better resolved and deeper reference image which would provide higher photometric precision. Fig. 5.12 shows PL diagrams of the VS candidates in the light of the newly derived PLR distance.

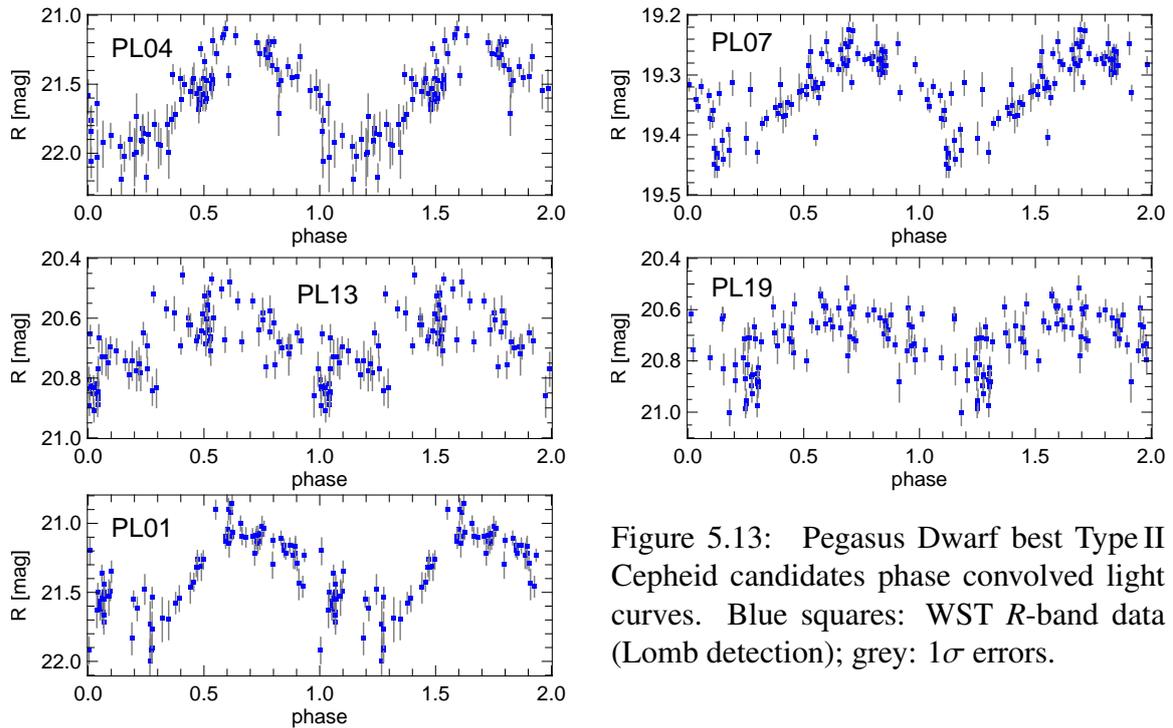

Figure 5.13: Pegasus Dwarf best Type II Cepheid candidates phase convolved light curves. Blue squares: WST R -band data (Lomb detection); grey: 1σ errors.

Since the cross-correlation of the wrongly classified variable candidates of Hoessel et al. [1994] for Leo A did not provide any further insight than one has to have sufficient sampling for period assessment and classification I did not repeat this painful exercise for the Hoessel et al. [1990] Pegasus VS candidates which also resulted in a wrong distance determination. However, Aparicio [1994] not only disproves the Hoessel et al. Cepheids but also lists what he presumes to be valid Cepheid candidates from colour and observed variability between two nights but unfortunately fails to give coordinates for them; he also does not provide a proper finding chart but only a diagram displaying positions and brightness of his sample of 1270 stars in Peg DIG. Nevertheless, by comparing this diagram with the Fig. 5.14 finding chart one can surmise that PM02, PM03, PM04, PM05, and PM09 are identical with five of his six δ Cephei candidates. Again, it is most unfortunate that the diagram does not explicitly identify those candidates in the according photometry table, but, since his brightest candidate has $R = 21.36$, which also sets the limit for PM03, and the Aparicio [1994] data had below $0.6''$ seeing, the assumption that PM03 is indeed brightened by a “blue blend” is strengthened³⁶. For similar reasons one might argue that the photometry of PM09 is hampered by a “red blend”.

³⁶Unless, off course, the according observations exactly met the minimum of the light curve.

Longer period “Cepheid” candidates

Most of the longer period Type II Cepheid candidates of Tab. 5.6 can be classified as “red” LPVs or Mirae²¹ stars; PL01 is an typical example of those. However, it is intriguing that the brightness of the bulk of those objects coincides with the TRGB since Mirae stars are thought to be Post-AGB objects. Also, the completeness tests for Peg DIG (Fig. D.1) show that our data is sensitive to lower limits than indicated by the “cloud” of the LPVs in Fig. 5.9 or the peak of the histogram in Snigula [2006], Fig. 4.8. The average amplitude of those LPVs is also smaller (< 1 mag) than one would expect for bona fide Mirae stars³⁷. The shape of their light curves is often enough noisy but would still be compatible with RV Tauri or W Virginis. This group does not correlate with a Type II PLR (Eqn. 1.4) but instead intersects it at about 30 d for our $m - M = 24.72 \pm 0.24$ mag distance modulus. The four bluest VS (Fig. 5.9, left most red circles) of Tab. 5.6 coincide with the instability strip indicated by the shorter period (Fig. 5.9, left most green circles) δ Cepheid candidates. Of those three, PL04, PL13, and PL19 are also perfectly consistent with the “redder”, Eqn. (1.4) Type II PLR (Fig. 5.12, red line) at our distance. PM14*a* is also perfectly aligned with the relation but already too faint to give either colours or a clear light curve shape. PL07 (topmost cross in Fig. 5.12, right bottom) partly resembles LL01: It is consistent with the “bluer”, Eqn. (1.4) Type II PLR (Fig. 5.12, purple line) and also has a RV Tauri compatible light curve but with a low amplitude. However, its colour would more point towards its classification as a Mira star. But remember, this can very well be due to the caveat for colours raised in the very first paragraph of Sect. 5.2.1 and which is even more true for long periods.

While our data does not provide evidence beyond doubt it indicates that either known variable stars classes have peculiar features in extremely metal poor environments or those environments actually provide us with different types of variable stars.

³⁷And still small if all were of the smaller than Mira amplitude SRa type which is their closest matching classification.

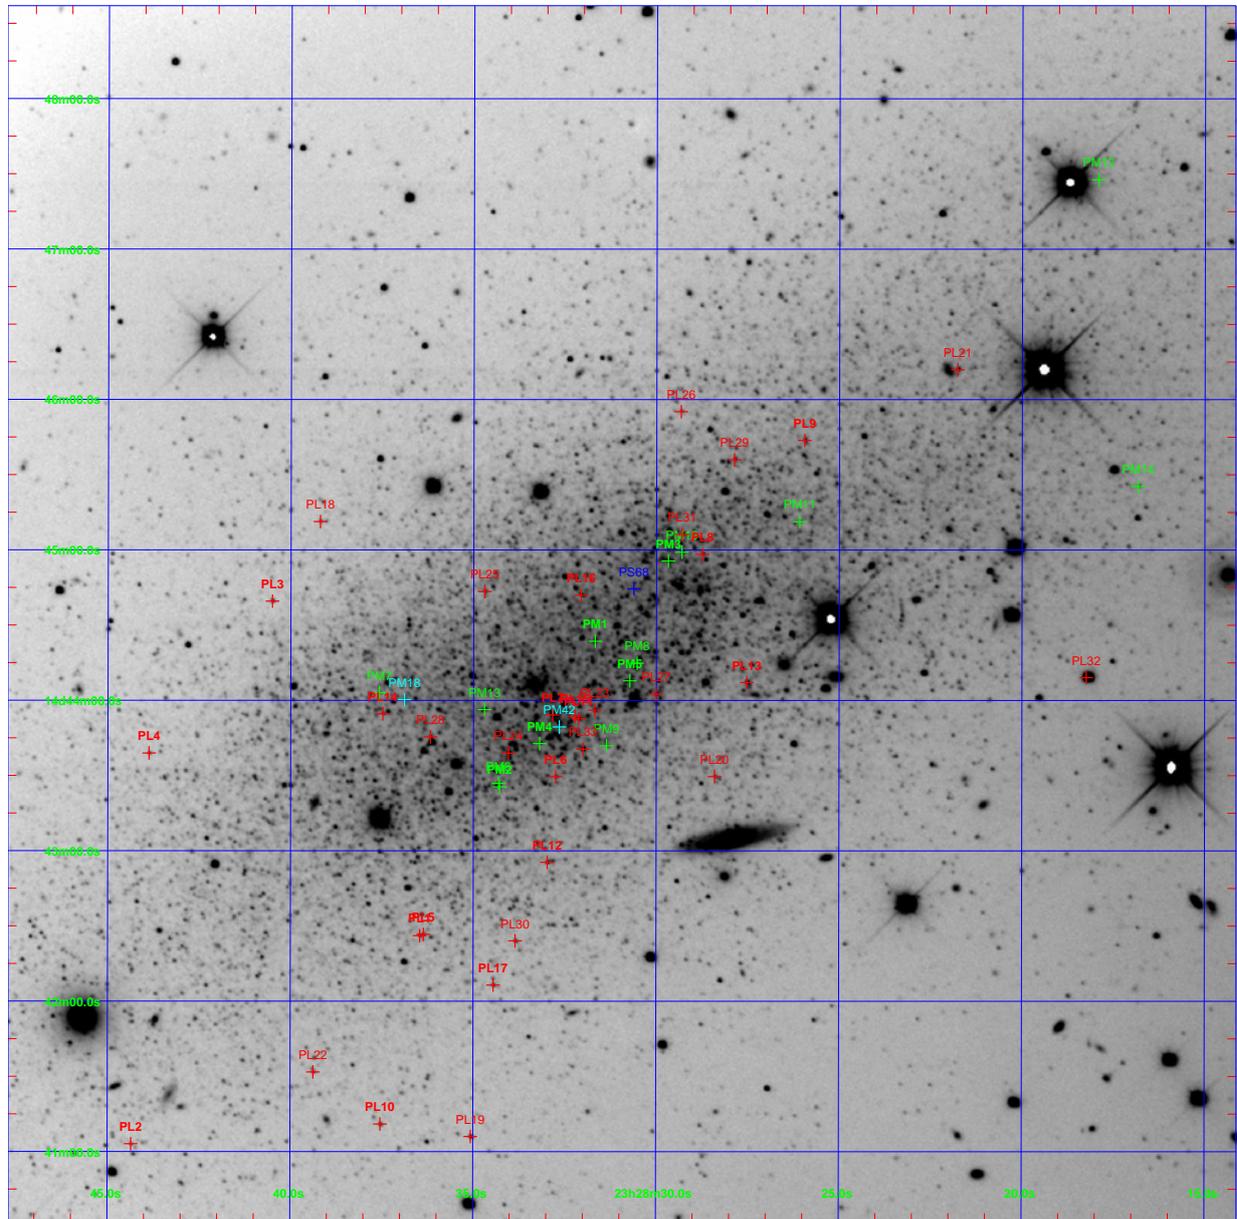

Figure 5.14: Finding chart of selected VS candidates, mostly of Tab. 5.5 and 5.6 but partly also from Tab. F.1. Blue and turquoise: LS and LM short period pulsating B-star candidates; green: LM most promising δ Cephei candidates; red: LL long period Type II Cepheid candidates.

5.2.3 EGB 0427+63 – A Miss

The story on this (most probably not Local Group) Dwarf remains short: It turned out to be beyond the reach of our little telescope, at least for all kinds of Cepheids. Mateo [1998] still lists it with $m - M = 25.6$ which seemed already a hard task to prove by variable stars with

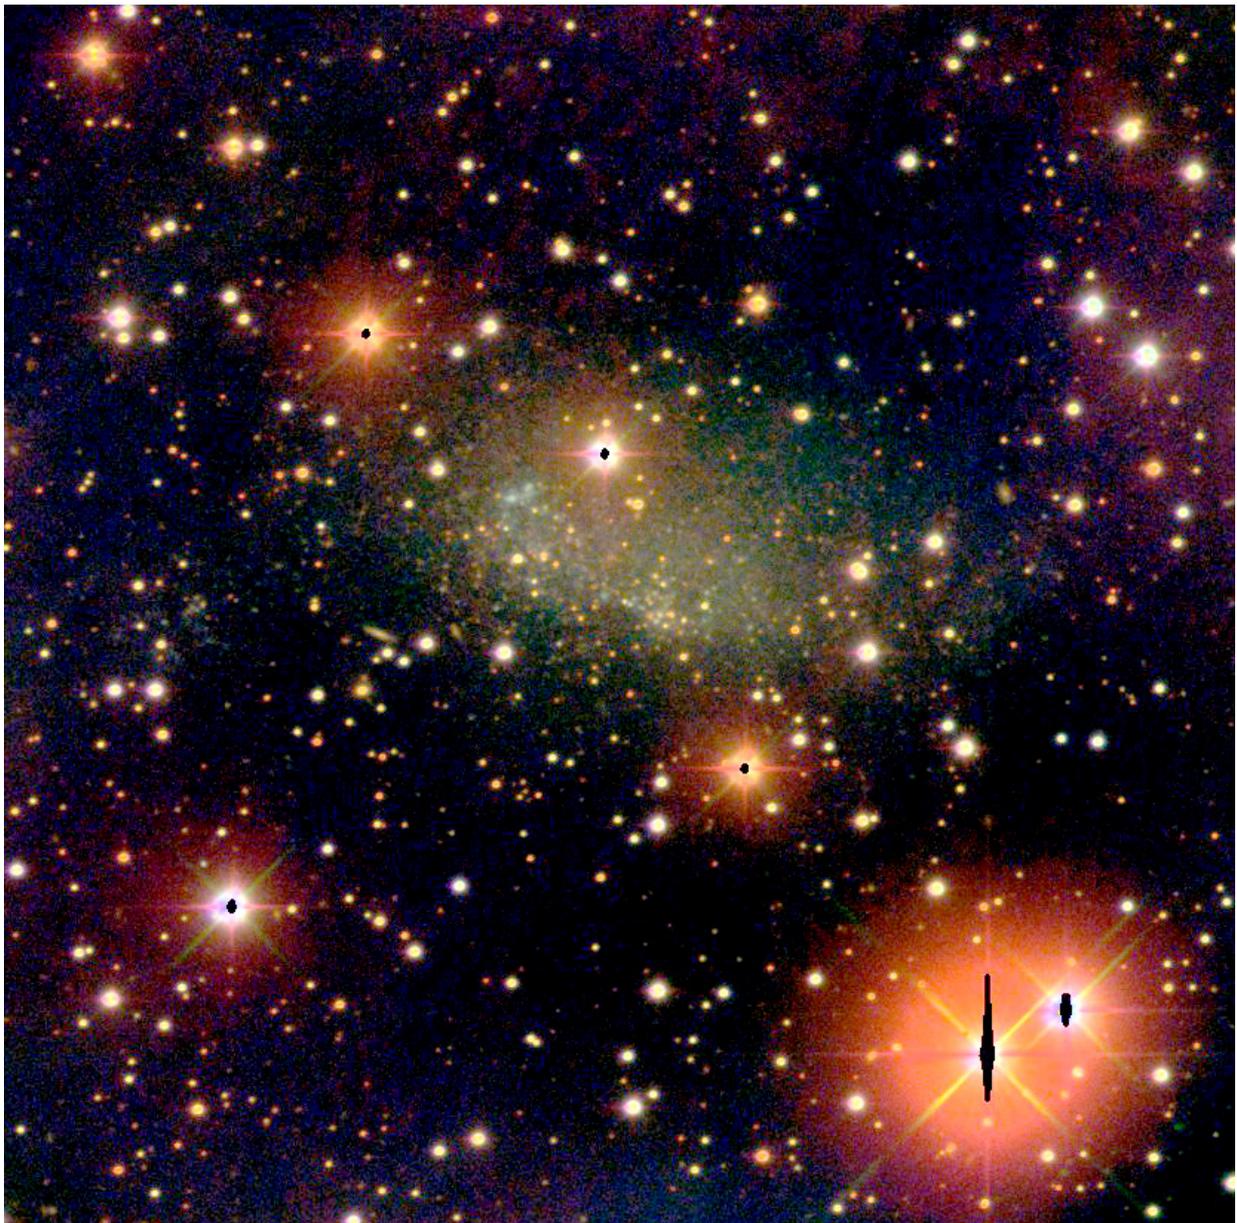

Figure 5.15: Colour composite image of EGB 0427+63: Red channel = CA *I*-band reference image, green channel = WST + CA *R*-band reference images, blue channel = CA *B*-band reference image; exponential scaling.

our equipment, especially when combined with its high galactic extinction [Schlegel et al., 1998, $A_R = 2.118$]. But as it easily showed up with 30 min exposures during test observations and as there was no dwarf competing at its RA (Tab. 2.1) we started observations. Fig. 5.16 shows a finding chart and CMD and PL diagrams of this dwarf and the VS candidates (Tab. F.6 and F.7) we found in the vicinity; all stars brighter than ~ 19.5 mag are most likely galactic foreground objects and not at all associated with the dwarf³⁸. Also shown is a PL diagram with a extinction corrected Madore and Freedman [1991] R -band PLR at a Karachentsev et al. [2006] distance ($m - M = 27.39 \pm 0.18$ mag). The latter clearly shows that there is nothing to win here for us concerning

³⁸EGB 0427 has only a galactic latitude of $+10.5$ deg.

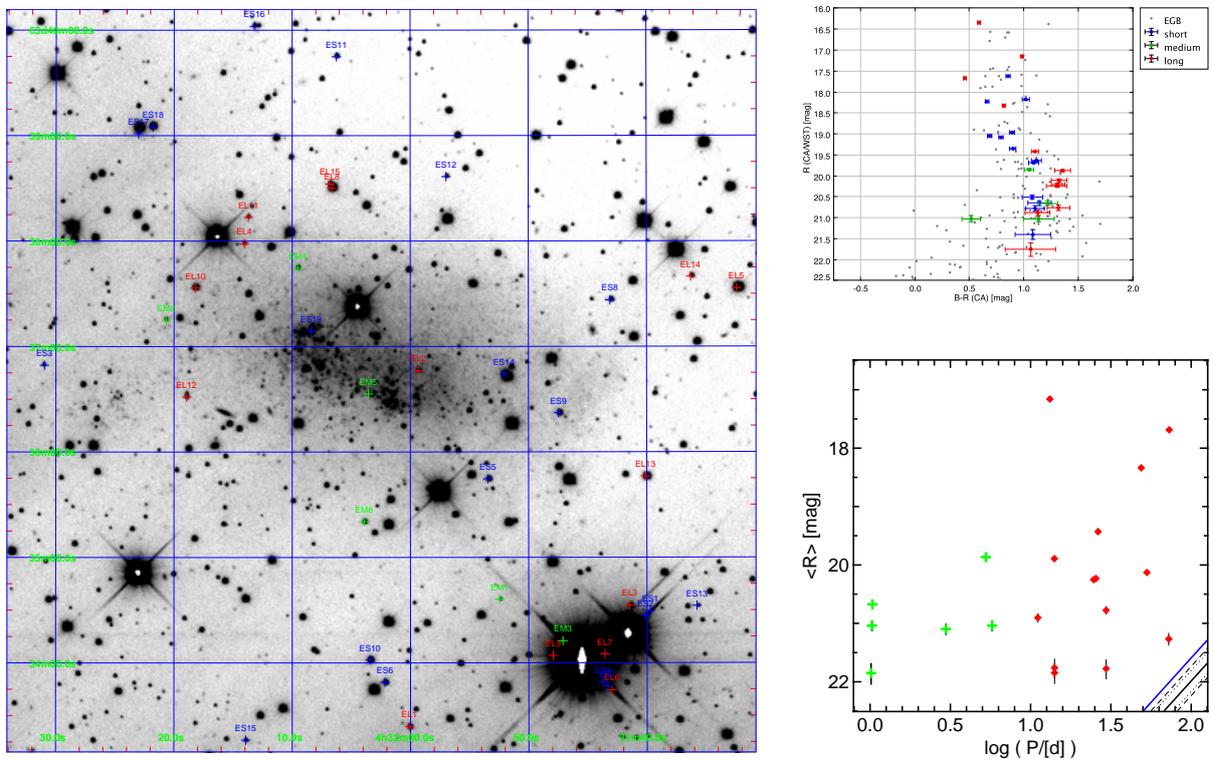

Figure 5.16: EGB 0427+63 finding chart, CM and PL diagrams. Blue markers: short period ($P < 1$ d) VS candidates; green markers: intermediate period ($1 \text{ d} < P < 10$ d) VS candidates; red markers: long period ($P > 10$ d) VS candidates. CMD grey: CA R -band (uncorrected) vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998, $A_R = 2.118$, $A_B = 3.419$); CMD other colours: WST R -band (uncorrected) and propagated errors vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998) and DAOPHOT errors. PL diagram solid black line: R -band period-luminosity relation for fundamental mode LMC Cepheids, Eqn. (1.3) [Madore and Freedman, 1991] corrected for galactic extinction [Schlegel et al., 1998, $A_R = 2.118$] and shifted to the Karachentsev et al. [2006] TRGB distance ($m - M = 27.39 \pm 0.18$ mag); PL diagram dotted black lines: TRGB distance error; PL diagram dashed black lines: PLR error; PL diagram solid blue line: First Overtone relation after Eqn. (1.5).

Cepheids. Nevertheless, EM05 might be a candidate for a variable B-star (leftmost green circle in the CMD), and even more all the LPVs with $R \approx 20$ mag and fainter, $B - R$ colours redder than 1.0, and associated with the dwarf are valid candidates for AGB variable stars (EL02, EL04, EL11, EL12, EL15, and maybe still EL14; Tab. F.7). However, to reasonably apply the same techniques that worked for Leo A and the Pegasus Dwarf with an 80 cm telescope one would require 8 m class telescope observations.

Figure 5.17: Colour composite image of GR 8 (looks as the name says): Red channel = CA I -band reference image, green channel = WST + CA R -band reference images, blue channel = CA B -band reference image; exponential scaling.

5.2.4 GR 8 – Surprise

Fortunately for us GR 8 turned out to be somewhat nearer than EGB 0427+63 and, of course, suffers much less from galactic foreground extinction because of its much higher galactic latitude. Our CMD (Fig. 5.18, left) of this compact looking dwarf indicates very previous star formation, the brightest end of a blue main sequence (“blue plume”) is discernible though sparsely populated; the RGB and its tip are still clearly visible. Comparing the R -band TRGB of Leo A (Fig. 5.2 ~ 21.0) with that of GR 8 (~ 23.0) one would assume a 2 mag greater distance for the latter which perfectly matches the results of our δ Cephei PLR distances (see Sect. 5.2.1 and below). I was able to recover the δ Cephei star previously discovered by Tolstoy et al. [1995, $m_{<r>} = 22.12$ and $P = 16.166$ d]. GL01 actually is by far the most significant variable source in the GR 8 field (Tab. 5.7, Fig. 5.19, and Fig. 5.20). GL02 turns out to be a blend of GL01³⁹; since it does not match with a blue resolved source it gets the colour of GL01 assigned as this is the closest positional match and still within the matching boundaries⁴⁰. From our measurements I derive a distance modulus of

$$\text{GR 8 } m - M = 26.45 \pm 0.07 \pm 0.06_{\text{ZP}}(\pm 0.25_{\text{PLR}}) \text{ mag.} \quad (5.3)$$

The Tolstoy et al. [1995] “longer” period and fainter brightness explain their larger derived distance modulus ($m - M = 26.75 \pm 0.35$). GL03, while in agreement with Type II Cepheid PLRs, is actually too red for that kind of VS and falls into the Mira regime in terms of colours. GL05 also coincides with a Type II Cepheid PLR but now is too blue and most probably just caused by a “lunation” window function as GL04 and GL06 suggest. Both are also plotted in the PL diagram (Fig. 5.18) but not associated with GR 8 and lie outside the Fig. 5.20 field of view.

³⁹Red circle right below the green circle and the black cross in Fig. 5.18, CMD and PL diagram respectively.

⁴⁰The distance is less than 2”.

Table 5.7: Parameters of GR 8 δ Cephei $1 \text{ d} < P \leq 130 \text{ d}$ period candidates: Short identifier (see Fig. 5.20), IAU compliant identifier, position, most significant Lomb period(s), significance (p -level), flux averaged apparent R -band magnitude, r.m.s. error of R -band magnitude.

GS04, the bluest VS in the CMD (Fig. 5.18) is a viable β Cephei candidate which, if it could be confirmed, again, would raise the question of either the host’s metallicity, the instability region for B-stars or maybe even the main sequence evolution of metal poor B-stars.

GS01a comes uncalled for and as a big surprise: Its colour, brightness and light curve denotes it as an α Cygni type variable star, i.e. “[...] quasi-periodic A type supergiants having amplitudes of about 0.1 magnitudes and periods of days to weeks [...]” [Becker, 1998]. Because of their short life time A-giants are already very rare in dwarf galaxies, even in dIrrs. One would expect to more or less “always miss” evolved A-stars in *VarStarDwarves* like galaxies. The finding of such an intrinsically very bright star in a extremely metal poor environment as GR 8 in our “extended neighbourhood” allows to take a closer look on a type of star which contributes most to the light of high redshift star forming galaxies. It also may show if and how the huge stellar wind of this metal poor variant of such a star can affect interstellar feed back and metal enrichment of its environment.

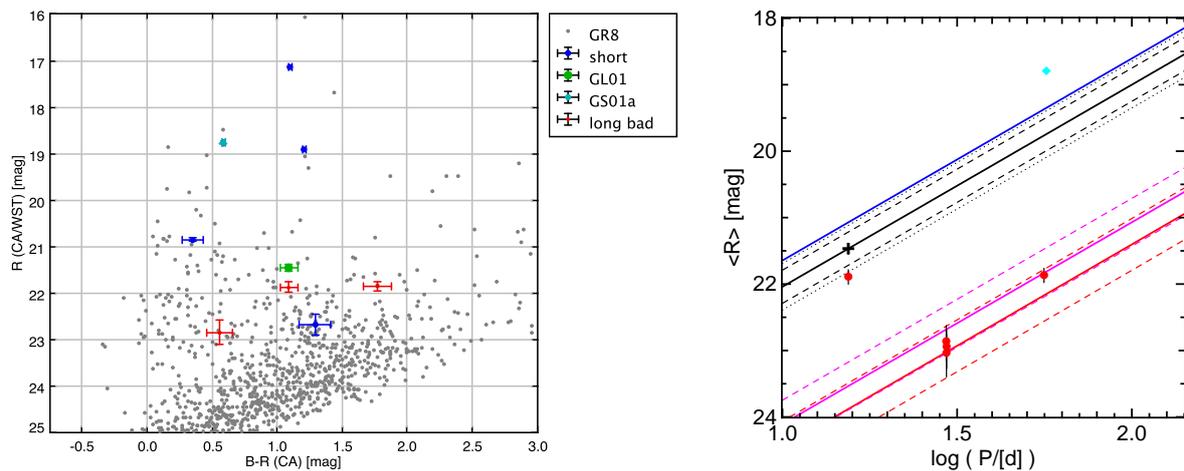

Figure 5.18: GR 8 CM and PL diagrams. Blue: short period $P < 1$ d VS candidates; turquoise: GS01a LBV candidate; green: GL01 most promising δ Cephei candidate; red: worse ($p > 0.01$) long period Cepheid candidates. CMD grey: CA R -band (uncorrected) vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998, $A_R = 0.070$, $A_B = 0.113$); CMD other colours: WST R -band (uncorrected) and propagated errors vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998) and DAOPHOT errors. PL diagram solid black line: R -band period-luminosity relation for fundamental mode LMC Cepheids, Eqn. (1.3) [Madore and Freedman, 1991] corrected for galactic extinction [Schlegel et al., 1998, $A_R = 0.070$] and shifted to match our GL01 photometry and period assessment ($m - M = 26.45 \pm 0.07 \pm 0.06_{ZP} (\pm 0.25_{PLR})$ mag); PL diagram dotted black lines: TRGB distance error; PL diagram dashed black lines: PLR error; PL diagram solid blue line: First Overtone relation after Eqn. (1.5). PL red and purple lines denote Type II PLRs and their errors (Sect. 1.5.4, Eqn. (1.4) and (1.5)).

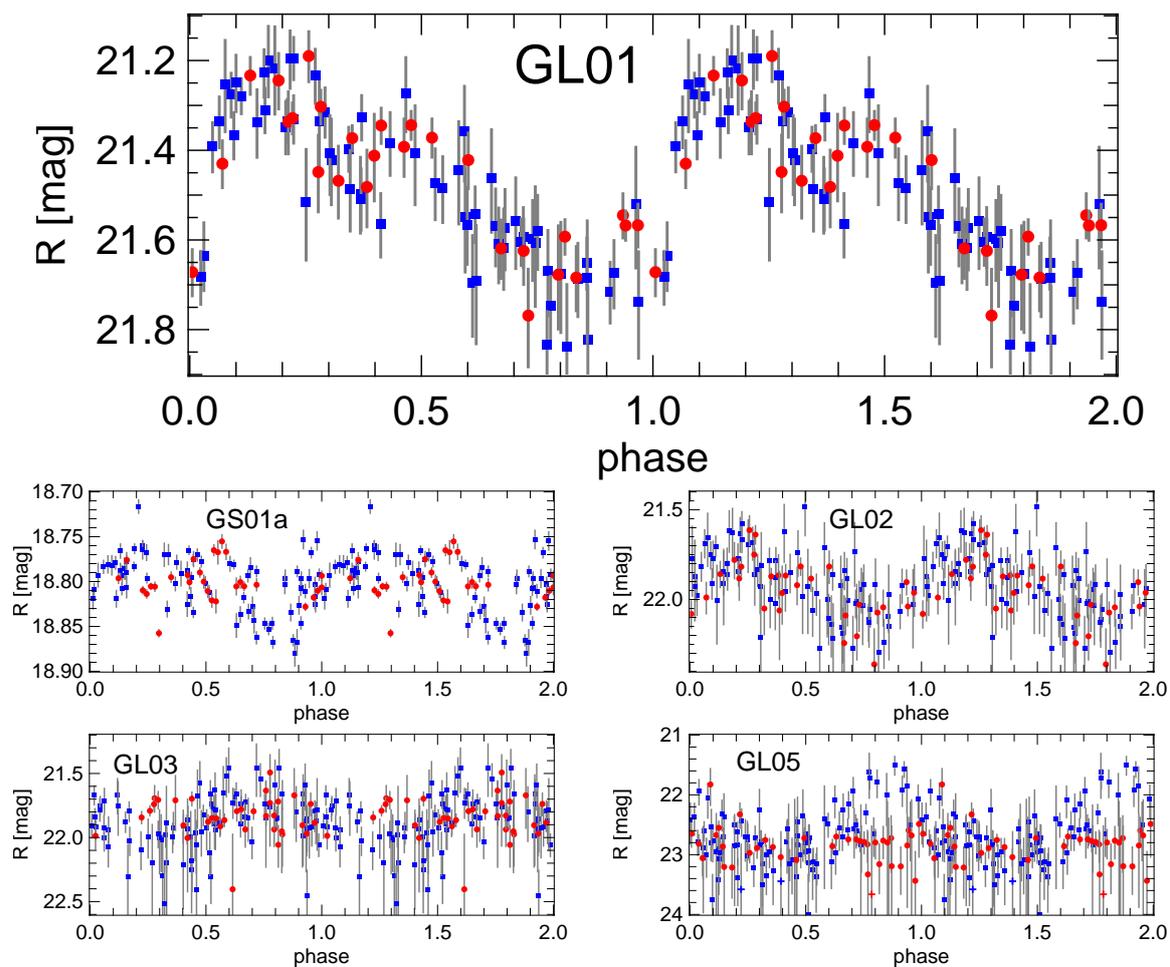

Figure 5.19: GR 8 best VS candidates phase convolved light curves. Blue squares: WST data (Lomb detection); red circles: CA data (consistency check); coloured crosses: Data consistent with detection limit at epoch, i.e. $S/N < 1$ at either site; grey: 1σ errors.

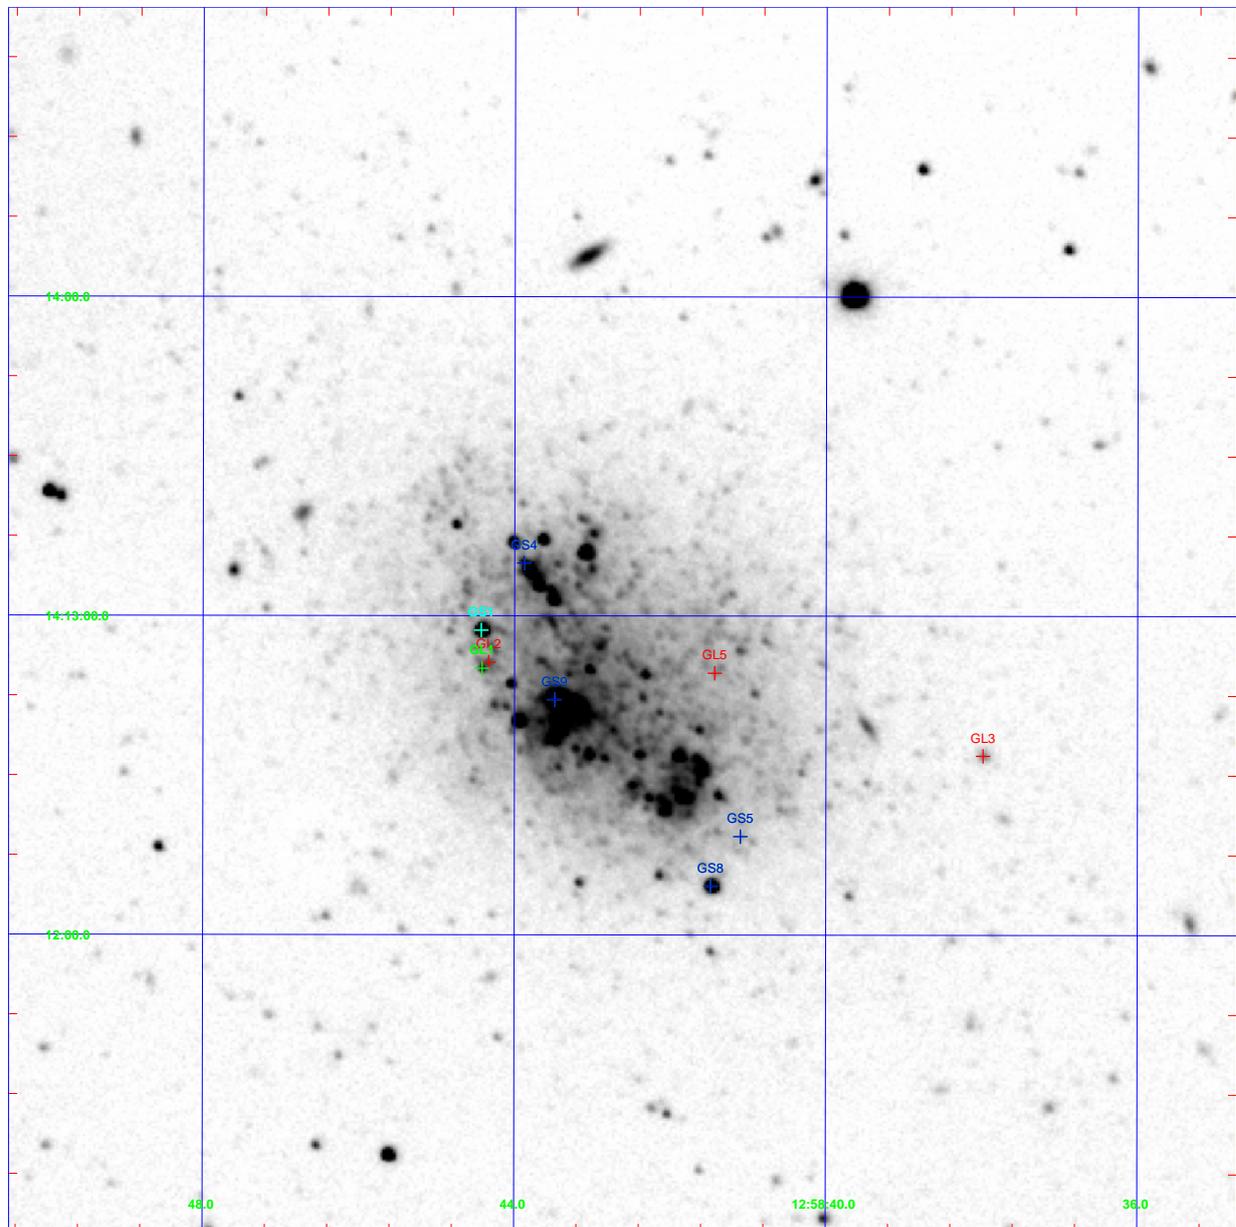

Figure 5.20: Finding chart of selected GR 8 VS candidates (Tab. 5.7 and F.8). Blue: short period $P < 1$ d VS candidates; turquoise: GS01a LBV candidate; green: GL01 most promising δ Cephei candidate; red: worse ($p > 0.01$) long period Cepheid candidates.

Figure 5.21: Colour composite image of the Aquarius Dwarf: Red channel = CA *I*-band reference image, green channel = WST + CA *R*-band reference images, blue channel = CA *B*-band reference image; exponential scaling.

5.2.5 Aquarius Dwarf – Mystery still

We do not have any deep enough reference frames⁴¹ besides the *R*-band to build colours and test if there are any candidates for pulsating B-stars among “the usual suspects” in the short period candidates (AS01, AS02, AS12, and AS14 in Tab. F.9 and Fig. 5.22, top). AM02 is consistent with a Madore and Freedman [1991] PLR shifted to the McConnachie et al. [2006] distance ($m - M = 25.15 \pm 0.08$ mag, Fig. 5.22, bottom right). The secondary power peak of AS06a gives a solution which may still be consistent with the according First Overtone relation, and AS06 is probably still associated with the dwarf (Fig. 5.22). (AM01 and AS03 are associated with background galaxies and may actually be due to window functions “excited” by AGNs⁴².)

Nevertheless, the overall data is inconclusive and suggests a different observing strategy for this galaxy: About six “half” nights randomly spread over two weeks with a 2 m class telescope at a more southern observatory should be sufficient to detect (or confirm) shorter period δ Cephei candidates. The complete absence of any bright longer period stars [Snigula, 2006, Sect. 6.5], however, remains puzzling and either indicates a longer distance or a very strange star formation history⁴³.

⁴¹Because of the objects low declination and its best visibility during the short summer nights good enough observing conditions were too rare to go for an additional waveband at WST. We also have only very little CA observations. (See also Tab. 2.3.)

⁴²Active galactic nuclei.

⁴³I.e. a combination of an ancient population which does not produce any bright AGB stars any more and a very young population which still would not produce a sufficiently high amount of AGB stars.

Table 5.8: Parameters of Aquarius δ Cephei $1 \text{ d} < P \leq 130 \text{ d}$ period candidates: Short identifier (see Fig. 5.22), IAU compliant identifier, position, most significant Lomb period(s), significance (*p*-level), flux averaged apparent *R*-band magnitude, r.m.s. error of *R*-band magnitude.

Id	IAU compliant name	RA-2000 [h]	Dec-2000 [deg]	period [d]	signific. [<i>p</i>]	$\langle R_f \rangle$ [mag]
AM01	WST J204646.4-125219	20:46:46.367	-12:52:18.60	1.033	1.38e-01	18.89±0.02
AS06a	WST J204701.4-125041	20:47:01.448	-12:50:40.82	2.030	1.52e-01	22.06±0.38
AM02	WST J204645.3-125036	20:46:45.309	-12:50:35.99	7.408	1.85e-01	21.48±0.22

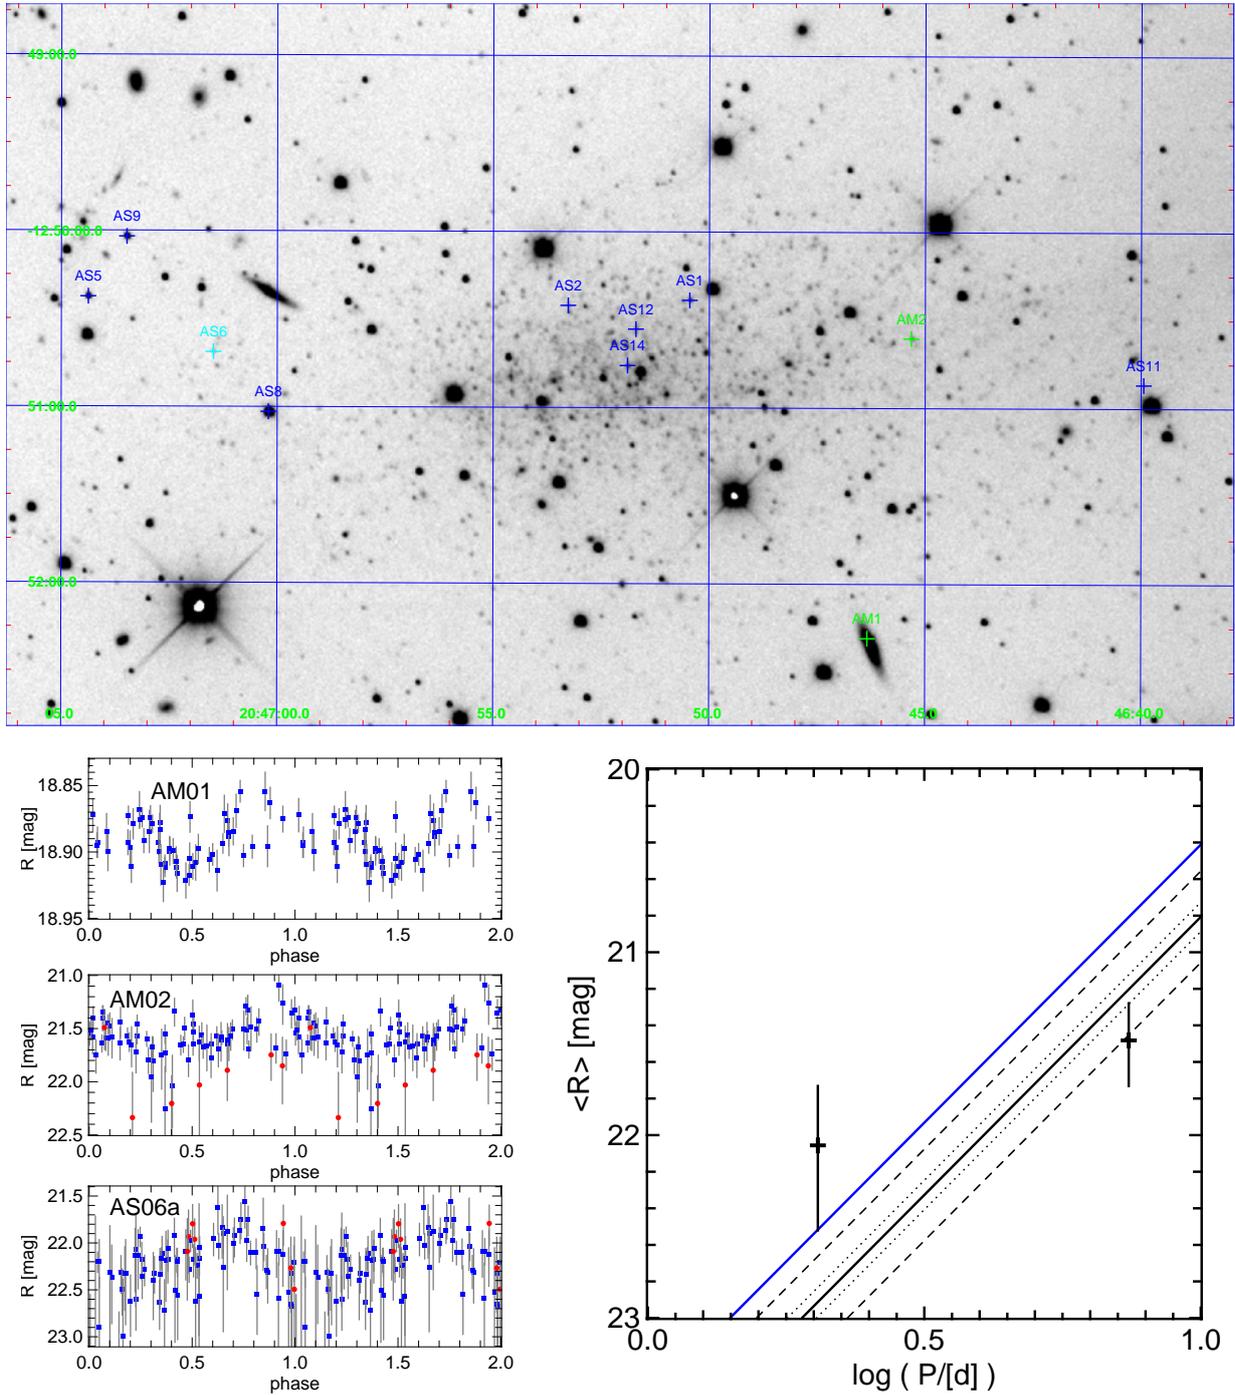

Figure 5.22: Aquarius Dwarf finding chart, light curves, and PL diagram. Top – Finding chart of VS candidates (Tab. 5.8 and F.9); remaining candidates are outside the FoV of the chart and probably not associated with the dwarf. Bottom left – period $P > 1$ d VS candidates light curves. Bottom right – PL diagram: Solid black line – R -band period-luminosity relation for fundamental mode LMC Cepheids, Eqn. (1.3) [Madore and Freedman, 1991] corrected for galactic extinction [Schlegel et al., 1998, $A_R = 0.137$] and shifted to the McConnachie et al. [2006] TRGB distance ($m - M = 25.15 \pm 0.08$ mag); dotted black lines – TRGB distance error; dashed black lines – PLR error; solid blue line – First Overtone relation after Eqn. (1.5); black crosses – AM02 and AS06a.

5.3 Summary

5.3.1 Status quo

The results regarding “bright, blue” Variable Stars from monitoring of the *VarStarDwarves* DGs for six years can be broken down into the following:

“Firm” results: The finding of four and five unambiguous classical δ Cephei variable stars in Leo A and the Pegasus Dwarf respectively allowed for the first time to establish accurate PLR distances to them (Eqn. (5.1) and (5.2)); they confirm recent TRGB distances by means of a completely independent method. At least another six VS candidates for each dwarf could enhance the δ Cephei samples but would require dedicated deeper, higher resolved, or multi-colour observations. Such observations would also enhance the error margin of the already confirmed samples as they would increase their signal-to-noise ratio and improve the deblending of the highly crowded fields. In GR 8 I was able to recover a previously found δ Cephei star and to derive from it a distance modulus consistent with recent publications (Eqn. (5.3)). The finding of an α Cygni VS in a local dwarf with its very metal poor environment is against all odds and may prove to be of value for astrophysicists, working on hot stars in general, and LBVs in particular, as it is accessible to spectroscopy with very large telescopes, though challenging.

Some speculation: Concerning possible RV Tauri stars in the Pegasus Dwarf, they resemble the Alcock et al. [1998] findings for the LMC RV Tauri which already has much lower than galactic metallicity: The PLR seems to steepen for longer periods and the stars’ amplitudes are small compared to galactic, higher metallicity RV Tauri. Looking at the even more metal poor Leo A dwarf this trend seems to progress: Its longest period RV Tauri is even more brighter than expected from a Alcock et al. [1998] PLR and its amplitude significantly smaller. This can be interpreted as follows: For the same period of a RV Tauri, as metallicity decreases also does its amplitude at the same time increasing its *R*-band brightness. This may very well be explained by just less metals and molecules in the envelope or outer atmosphere of the star or even simply less “dust” in the surrounding, already shed stellar envelope as we look at stars at the very end of their nuclear burning phase.

The finding of bona fide pulsating B-stars candidates in Leo A and Pegasus Dwarf (and possible candidates in GR 8 and EGB 0427+63) is puzzling and would, if they can be confirmed, have some repercussions on theory with three possible scenarios:

1. The main sequence evolution of very metal poor stars after a “zone of avoidance” at about LMC metallicity, again, enters the B-stars instability region.
2. The pulsation theory on B-stars and its derived instability strip is wrong for extremely low metallicity.
3. Unexpectedly and despite their shallow gravity well, isolated DGs, in contrast to DG satellites of bigger galaxies (like the Magellanic Clouds encircling the Milkyway Galaxy), can

retain some of their metals from previous star formation, at least in some regions of recent star formation.

However, the candidates may also turn out to be Eclipsing Binaries which then might allow to derive their system parameters as outlined in Sect. 1.5.5 and, in principle, could provide an independent means of distance determination. Such an eclipsing nature could be tested by looking for strictly periodic radial velocity variations.

5.3.2 Future Prospects

Of course, the questions raised in the previous paragraph “cry” for spectroscopic follow up observations which we have started by looking at the brightest RV Tauri and the brightest β Cephei candidate in Leo A with the 10 m HET telescope and its low-resolution spectrograph to get some hints on both their metallicity. All other candidates will be even more challenging but will be looked at if the brightest ones indicate interesting results.

We plan to share our finding of the α Cygni in GR 8 with specialists working in the field, at the same time looking for other, non-periodic LBVs in our sample which would not have turned up by Lomb periodograms but will still be visible in the variations mask selected samples. Of course we will at the same time look for other non-periodic or eruptive events.

There is also still existing data waiting to be analysed: We have not touched yet the 2006 and 2007 epochs due to limited resources, and the LGS 3 data right now slowly reach a suitable number of epochs to begin with evaluation for periods. As the quality of our observations (most importantly the images PSF FWHM) still improved over the last two years, higher resolving reference images can be constructed which will most certainly enhance the results of both, the difference photometry of individual epochs and the DAOPHOT deconvolution photometry of the reference.

Furthermore, we are thinking of trying a different approach which so far was not possible due to limited computational and storage resources. If we would build phase binned stacks for the whole range of possible periods before difference imaging we could avoid Lomb periodograms at all as only sources with periods close to the test period would show up in the variations mask. The former window functions would identify themselves as a largely inhomogeneous sample of phase stacks per period test. This approach would also allow us to attack very short periods in the order of less than half an hour as we can take advantage of the short individual exposures of three minutes.

Due to the long and repeating monitoring we are also on the edge of being able to resolve secular trends of the observed periods. This is of great interest as it would allow an estimate of the “speed of evolution” as stars move through the instability strip, e.g. for metal poor blue loop stars. Also, if the period of RV Tauri stars would always change in the same direction this would finally settle the issue if they really are post-AGB objects.

To conclude, local dwarf galaxies like the *VarStarDwarves* ones and especially their VS content, despite being rather faint objects, still have a “bright” future for observations⁴⁴.

⁴⁴... and if they were not all rounded up by some evil “Major Merger” they lived on happily ever after...

Appendix A

Guiding Camera Server

A.1 Commands for the ST7 Guiding Server

All commands are case-insensitive (READ == read == ReAd == ...) except for **x** and **xx**.

openwindow hostname:displaynumber.screennumber (i.e. deepthought:0.0) Opens server side graphicwindow on hostname. The server must run with tty connected to it. The client must have set "xhost +st7host" (whatever this may be). **This may be a severe security hole, just use with caution.**

closewindow shuts down server side display window

get *item* where *item* can be one of the following

binning	status of binning
ccd	status of imaging and tracking ccd
dither	show selected dither grid spacing
exptime	show selected exposure time [s]
fan	fan status [on/off]
guideangle	show rotation angle of guiding field
guiderate	show guide rate ["/s]
led	led status [on, off, fast blink, slow blink]
relay	show status [on/off] of all 4 relays
save	show server side save file status
shutter	shutter status
temp	show temperature settings

set *item value* where *item* is one of the following

binning #	binning factor: 1, 2 v 3 for imaging ccd
ccd ???	set active ccd, ??? = IMAGING v TRACKING
dither ###.##	set dither grid spacing in arcsec
exptime #####.##	set exposure time in seconds
fan ???	off, on
guideangle ###.##	set rotation angle of guiding field
guiderate ###.##	set guiding rate
led ???	off, slow, fast, on
relay ?? ###.##	turn on relay ?? [X+, X-, Y+, Y-] for ###.## s
save ??	on/off, set server side save file status
shutter ???	open, close, init
temp ???	set temperature control [value in deg C, on, auto, off]

expose start an exposure (darks are automatically determined and subtracted)

autoexpose start an infinite series of exposures, abort with **abort**

check_star [x, y] check star at coordinates x, y and show the results; if no x, y are given, star must be clicked in server side window; if no x, y are present and no server side window open, trying to use old coordinates

focus start focus series with last selected star via check_star (darks will be set on)

autoguide start guiding with last selected star via check_star; guiding will not be started unless a valid star already has been selected with check_star x y (darks will be set on)

abort abort exposure or guiding

dither move to next position on the dither grid

x close connection

xx close connection and end server (camera settings will not be altered)

Responses from server:

Command accepted: **READY: ...** where ... say what has been done.

Command denied: **ERROR: ...** where ... tell what specific error has been encountered.

Initialisation message (several strings): returns all hardware info of the camera

Settings messages:

BINNING: # x #	selected binning factor
CCD: [status of both ccds]	
DARK: [on or off]	status of auto dark subtraction
DITHER: ### ”	selected dithering grid spacing in arcsec
EXPTIME: ###.# s	selected exposure time in sec
FAN: [on or off]	status of fan
GUIDEANGLE: ###.##	selected rotation of guide field in deg. (0=N)
GUIDERATE: ###.## ”/s	selected guide rate in arcsec / sec
LED: [on, slow blink, fast blink or on]	led status
OFFSET: ### x ###	pixel offset of lower left corner
RELAYS: +X = [off or ##.##s], -X = [...], +Y = [...], -Y = [...]	status of relays
SAVE: [on or off] (... filename)	server side save option status
SHUTTER: [open, closed, ...]	status of shutter (not sent by exposures!)
SIZE: ### x ###	size of actual window in pixel
TEMP: regulation = [on or off], current = ##.# % of max., fan = [on or off] set = ###.# deg C, ccd = ###.# deg C, air = ###.# deg C	Temperature settings, 2 seperate strings

Image analysis messages (5 seperate strings each):

MINIMUM: ###	minimum value in image
MAXIMUM: ###	maximum value in image
MEDIAN: ###	median value in image
AVERAGE: ###.##	average value in image
STDDEV: ###.##	stddev. in image
REFERENCE STAR: sigma of fit = ##.#	
position: x = ##.##, y = ##.##	
fwhm: x = ##.### (##.### ”), y = ##.### (##.### ”)	
amplitude = ###.##, surface = ###.##	
angle = ###.#	or
ACTUAL STAR: sigma of fit = ##.####	
position: x = ##.## (d ##.##), y = ##.## (d ##.##)	
fwhm: x = ##.### (##.### ”), y = ##.### (##.### ”); (##.# %)	
amplitude = ###.# (###.# %), surface = ###.# (###.# %)	
angle = ###.# (d ###.#)	

Special messages:

EXPOSING: [dark or image] type of exposure in progress
READOUT: [dark or image] type of readout in progress
DOWNLOAD: ##.##% download status
JPEG: sending image stream
JPEG: locally saving image to [absolute_path/filename]
CORRECTION: x = ##.###”, y = ##.###”
azimuth = ##.###”, declination = ##.###”
movement to be applied in camera and telescope
frame, 2 separate strings

A.2 Guiding camera server configuration file syntax

Syntax of the parameters, their default values and description for the guiding camera server configuration file:

Parameter	value	description
ST7_IPPORT	= 9997	// command and status IP port number
IMAGE_IPPORT	= 9996	// IP port number for server side X11 control
DITHER_IPPORT	= 9995	// IP port number for dither trigger and setting, // i.e. to be used by main camera control
PARALLEL_PORT	= 1	// parallel interface port number; change to 2 or 3 // if camera is connected not to LPT1
DARK_OK_TEMP_LIMIT	= 15	// [0.1°] temp. range within darks are treated as OK
CCD_WARM	= 80	// temperature offset in 0.1° above which the CCD // is considered warm so fan can be set off
RELAY_MIN_RESPONSE	= 0.25	// [s] minimal response time for relays
TEL_FOCUS	= 9.9	// [m] focus of telescope
TEL_AREA	= 0.596319	// [m ²] effective mirror area of telescope
FITBOX_SIZE	= 49	// [pixel] initial boxlength for Gaussian centroid fit // on stars
GUIDEBOX_SIZE	= 81	// [pixel] initial length of window used for guiding
GUIDESTAR_ZOOM	= 4	// zoom factor for display of guidstar
GUIDE_ORIENT	= -1.0	// -1 v 1, initial orientation of field (mirrored or not)
GUIDE_ANGLE_OFFSET	= 180.0	// constant angular orientation offset
SAVE_FILENAME	= /home/ftp/guider.jpg	// server side path for image saving

Appendix B

AMiGo Camera Server

B.1 AMiGo motor controller programs

The calls to all programs stored on the CyberPak [Cyb, 2001] motorcontrollers themselves follow below. They can be executed directly over the serial interface, via a telnet session to the IPC relay [Bec, 2006] on the preset port, or by sending a file with the commands through the camera server (App. B.2). Some complex commands, i.e. move guider field / focus to position and slit exposures, are constructed within the server daemon and only call appropriate subroutines.

Shutter control, main routines:

code	description	return message
@0	select shutter control	None
px 0	call initialisation routines and set default behaviour, runs automatically at power up	None
px 1	initialise unit (resets limits and moves to default positions)	<i>Ready: Shutter Init</i>
px 10	open blue shutter	<i>Ready: Shutter b open</i>
px 11	open red shutter	<i>Ready: Shutter r open</i>
px 12	open both shutters (synchronous mode)	<i>Ready: Shutter s open</i>
px 20	close blue shutter	<i>Ready: Shutter b closed</i>
px 21	close red shutter	<i>Ready: Shutter r closed</i>
px 22	close both shutters (synchronous mode)	<i>Ready: Shutter s closed</i>

Shutter control, subroutines:

code	description	return message
cal 2	init: power up & test limits	None
cal 3	init: move to default position & power down	None
cal 4	power up blue shutter motors	None
cal 5	power up red shutter motors	None
cal 6	power up all shutter motors	None
cal 7	power down blue shutter motors	None
cal 8	power down red shutter motors	None
cal 9	power down all shutter motors	None
px 13	blue pre-exposure sequence	None
px 14	red pre-exposure sequence	None
px 15	synchronous pre-exposure sequence	None
cal 16	blue pre-exposure subroutine	None
cal 17	red pre-exposure subroutine	None
cal 18	synchronous pre-exposure subroutine	None
px 13	blue post-exposure sequence	<i>Ready: Shutter b closed</i>
px 14	red post-exposure sequence	<i>Ready: Shutter r closed</i>
px 15	synchronous post-exposure sequence	<i>Ready: Shutter s closed</i>
cal 16	blue post-exposure subroutine	<i>Ready: Shutter b closed</i>
cal 17	red post-exposure subroutine	<i>Ready: Shutter r closed</i>
cal 18	synchronous post-exposure subroutine	<i>Ready: Shutter s closed</i>

Filter / guider control, main routines:

code	description	return message
@1	select filter / guider control	None
px 0	call initialisation routines and sets default behaviour, runs automatically at power up	None
px 1	initialises unit (reset limits and move to default positions)	<i>Ready: Filter/Guider Init</i>
px 31	move to central guider field position	<i>Ready: Guider Field</i>
px 101	select blue filter 1	<i>Ready: Filter b 1</i>
px 102	select blue filter 2	<i>Ready: Filter b 2</i>
px 103	select blue filter 3	<i>Ready: Filter b 3</i>
px 111	select red filter 1	<i>Ready: Filter r 1</i>
px 112	select red filter 2	<i>Ready: Filter r 2</i>
px 113	select red filter 3	<i>Ready: Filter r 3</i>

Filter / guider control, subroutines:

code	description	return message
cal 2	init: power up & test limits	None
cal 3	init: move to default position & power down	None
px 25	move to preset guider focus position power down focus motor	<i>Ready: Guider Focus</i>
px 35	move to preset guider field position power down field motor	<i>Ready: Guider Field</i>

B.2 Commands for the AMiGo camera server

The AMiGo camera server understands the following set of commands so far (see Sect. 3.4 for additional information):

expose *channel* expose channel [i.e. *blue*, *red* or *sync*]

set exptime *channel duration* set exposure time length to duration [s]

set imagetype *channel type* set imagetype to bias, dark, science or flat

set window *channel region* set window to xStart:xEnd,yStart:yEnd

set binning *channel x-bin y-bin* set binning to x-bin y-bin

uploadMCProgs *filename* send file to motor controller

init shutter initialize shutters of both channels

init filter initialize filter of both channels and guider focus + field

set filter *channel position* sets filter of channel [here only *blue*, *red*] to position [1, 2, or 3]

set guider focus *position* sets guider focus to position [mm, 0 – 15]

set guider field *position* moves guider to field position [mm, -20 – +20]

help shows help on commands

These commands can be issued on the admin and on the client port. Finished commands return *Ready: [issued command]*

on the issuing port. Erroneous commands return a

PROTOCOL error: [Missing parameter ... ||Unknown command + issued command].

Listener messages

Clients connected to the listener port get the current status every second. The actual messages syntax also depends on the configuration file syntax.

```

Appendix E

By Chance Discoveries

E.1 Small Solar System Bodies

Table E.1: At the given dates and fields at least 8 detections of a fast moving object are available.

Field	Dates of nights with fast moving objects
Leo A (WST)	2000-01-11, 2000-01-12, 2000-02-27, 2000-02-27, 2000-05-02, 2000-11-30, 2002-02-14, 2002-03-10, 2002-04-02, 2004-12-06, 2005-02-07
Leo A (CA)	2001-02-01, 2001-02-12, 2002-02-01, 2002-02-10, 2002-02-12, 2002-02-14, 2002-02-22, 2002-02-23, 2002-03-21, 2002-03-22, 2002-03-23, 2002-03-23, 2002-04-24
Pegasus (WST)	2000-10-23, 2001-08-01, 2001-08-26, 2003-10-15, 2003-10-15, 2003-10-15, 2004-12-14, 2005-10-08
GR 08	2000-01-31, 2002-04-02
Aquarius	2000-08-23, 2000-08-25, 2001-07-22, 2001-07-27, 2001-07-30, 2001-08-13, 2001-10-17, 2003-09-14, 2003-09-15, 2004-08-08, 2004-10-03, 2005-11-14, 2099-07-17, 2099-07-17

During evaluation of the difference images several Small Solar System Bodies were detected. Since we did not go for any follow-up observations we did not report them to the Minor Planet Center. They are reported in Tab. E.1 only for documentation in case we decide to report the data at a later time. Arcsec astrometry and 0.2 mag photometry is easily available.

E.2 High Proper Motion and Parallax Stars

Objects moving more than 0.1 arcsec within the total observed period were detected with difference imaging. If they were bright (< 20 mag) they even had to be flagged for the reference kernel calculation (Sect. 4.3) and of course to be removed from the astrometry reference list

(Sect. 4.2.9). A list of those stars could be easily compiled but was beyond the scope of our project.

E.3 Background SN in the Leo A (CA) field

While we did not explicitly search for eruptive variables I glanced over a list of frequently, highly significant ($> 10\sigma$) outliers which were mostly due to nearby stars (see previous Sect.) and a few very bright Mirae. In case of the rather densely sampled Calar Alto data set this also chanced a Supernova in a background galaxy to show up. Fig. E.1 shows the light curve of the event but more importantly also illustrates one problem with difference photometry, highly crowded fields, and magnitudes: Magnitudes, being the logarithm of a flux ratio, always refer fluxes to some “known” standard. Difference photometry is able to provide changes in flux, and, if properly calibrated, even as an absolute quantity. As convincing a light curve might seem, the apparent mean magnitude (and therefore, of course, also the light curve amplitude) might be no more than a guess or an upper limit because it relies on the photometry of a deconvolved image of blending sources as reference. This has to be taken into account when looking at magnitude light curves built of difference photometry.

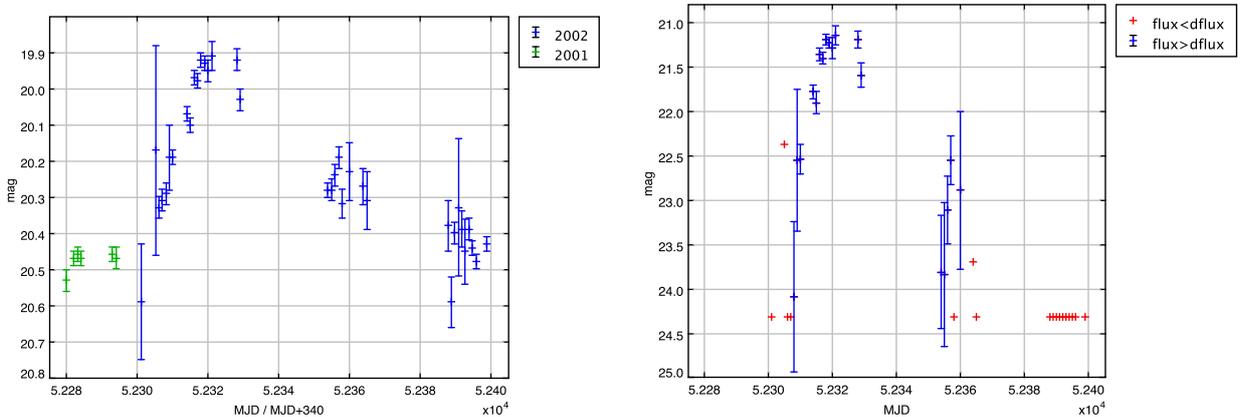

Figure E.1: The R -band light curve of a Supernova in a remote background galaxy. Left: Blue – apparent brightness with the local, unresolved galaxy background (≈ 20.45 mag per reference image PSF) as reference over Modified Julian Date $\text{MJD} = \text{JD} - 2400000.5$; green – data from previous year added with $\text{MJD} + 340$. Right: Blue – now referencing to zero flux displaying a pure “excess” magnitude; the lower limit (24.3 mag) corresponds to the 1σ noise from the skylight background of the reference image, smaller fluxes are clipped to this value; red – excess flux smaller than flux error resulting in a formally infinite magnitude error.

Appendix F

Periodic Variable Objects Remaining Tables

The parameters of all periodic variable objects of Tab. 4.4 which are not listed in Sect. 5 can be found here.

Appendix G

Additional CMDs & Finding Charts

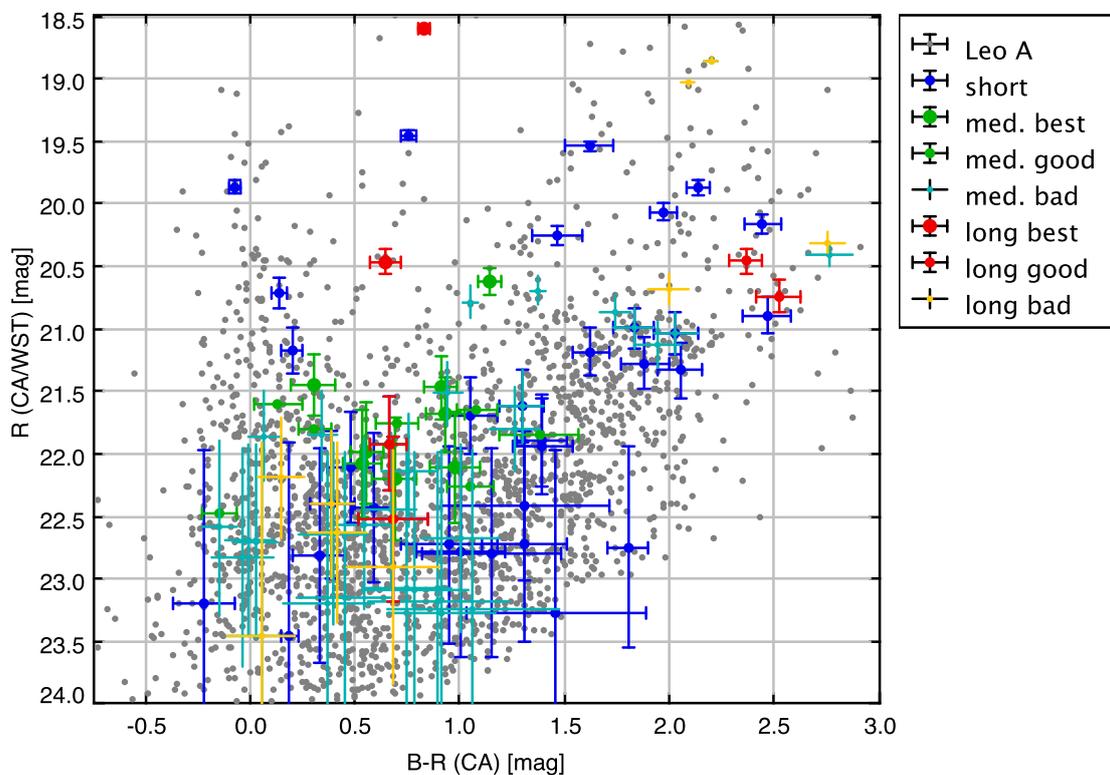

Figure G.1: Leo A CMD (all VS candidates)– grey: CA R -band (uncorrected) vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998, $A_R = 0.055$, $A_B = 0.89$); other colours (VS candidates): WST R -band (uncorrected) and propagated errors vs. CA $B - R$ colour (extinction correction after Schlegel et al., 1998) and DAOPHOT errors; blue: $P < 1$ d, $p < 0.25$, Tab. F.1; green: $1 \text{ d} < P < 10 \text{ d}$, $p < 0.01$, Tab. 5.1; turquoise: $1 \text{ d} < P < 10 \text{ d}$, $0.25 > p > 0.01$, Tab. F.2; red: $P > 10 \text{ d}$, $p < 0.01$, Tab. 5.2 top. yellow: $P > 10 \text{ d}$, $0.25 > p > 0.01$, Tab. 5.2 bottom.

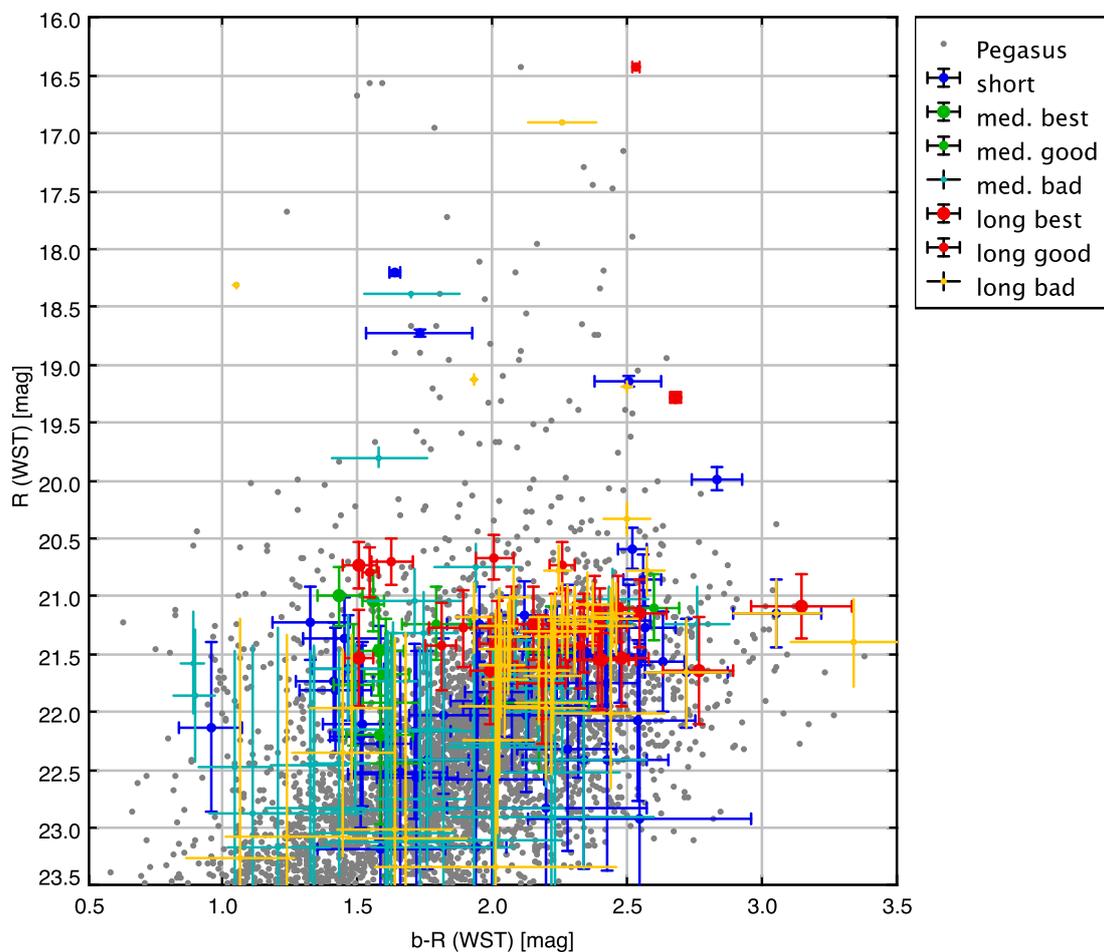

Figure G.2: Pegasus Dwarf CMD (all VS candidates) – WST R -band (uncorrected) vs. WST $b-R$ colour (extinction correction after Schlegel et al., 1998, $A_R = 0.176$, $A_B 0.284$); WST R -band propagated brightness errors, WST $b-R$ DAOPHOT colour errors. Please note the discussion of the WST b -band calibration and the derived colour in the text. Blue: $P < 1$ d, $p < 0.25$, Tab. F.3; green: 1 d $< P < 10$ d, $p < 0.01$, Tab. 5.5; turquoise: 1 d $< P < 10$ d, $0.25 > p > 0.01$, Tab. F.4; red: $P > 10$ d, $p < 0.01$, Tab. 5.6; yellow: $P > 10$ d, $0.25 > p > 0.01$, Tab. F.5.

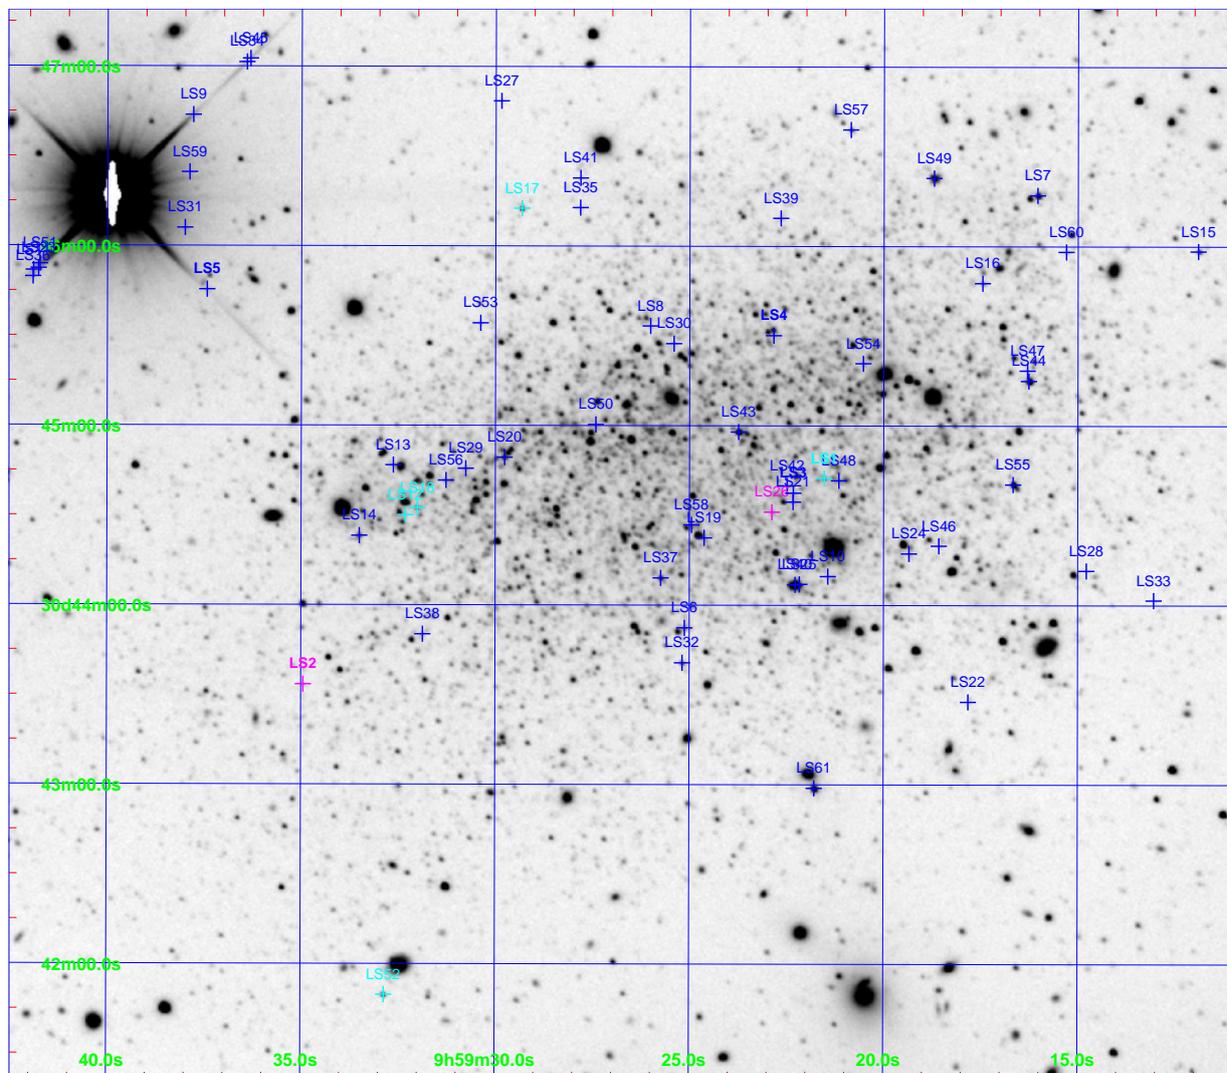

Figure G.3: Finding chart of shortest period $P < 1$ d VS candidates of Tab. F.1. Bold: high Lomb significance $p < 0.01$; blue: LS short period pulsating B-star candidates; cyan and magenta: Candidates with interesting secondary period solutions.

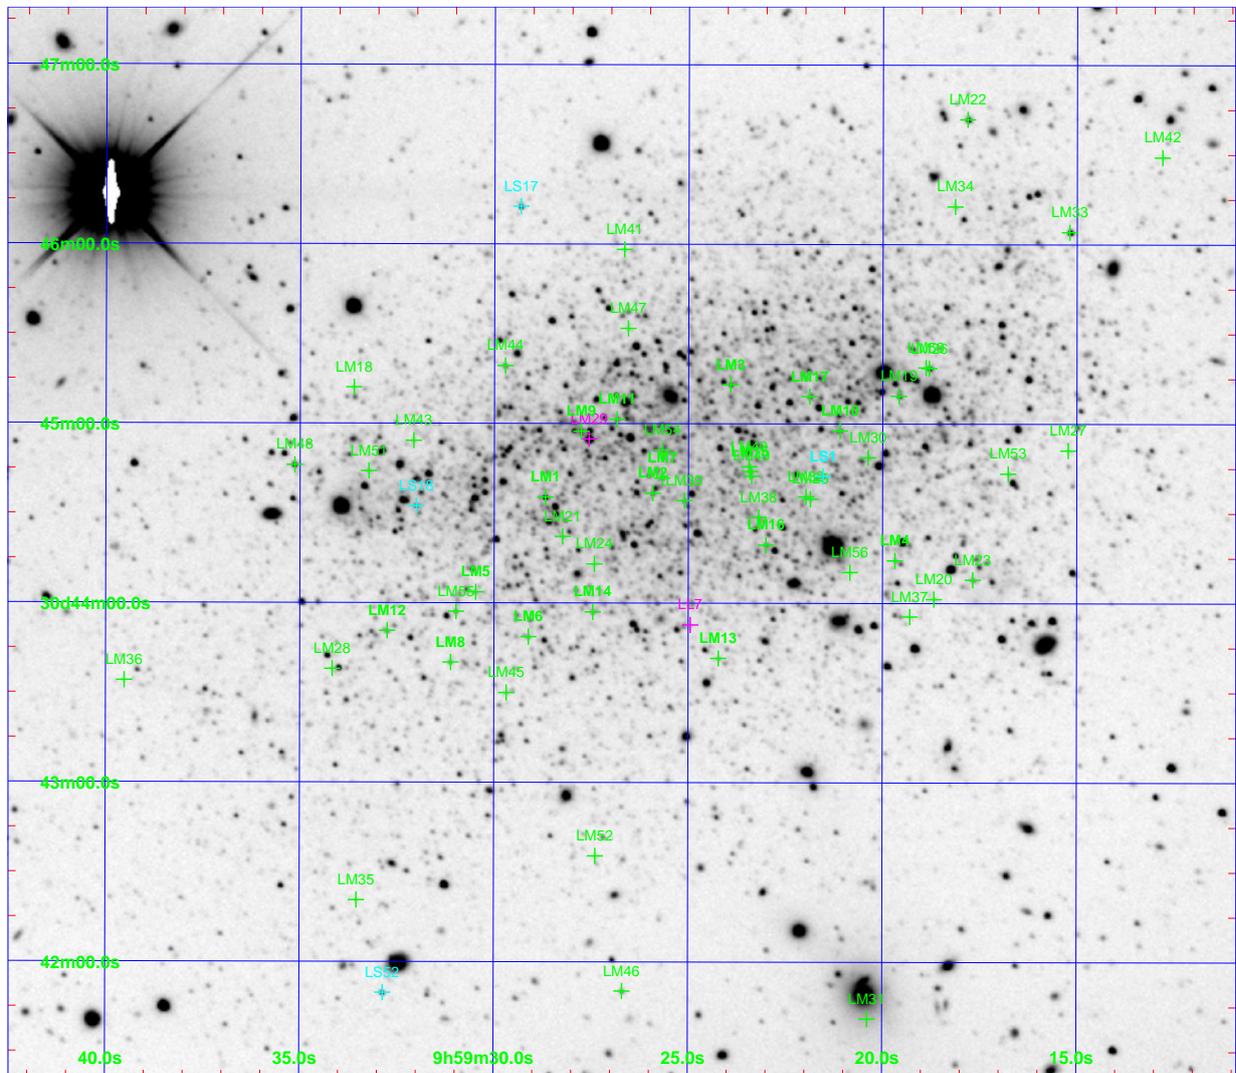

Figure G.4: Finding chart of $1d < P < 10d$ candidates, mostly of Tab. 5.1 and F.2 but partly also from Tab. F.1. Bold: high Lomb significance $p < 0.01$; green: LM promising δ Cephei candidates; cyan and magenta: Candidates with interesting secondary period solutions.

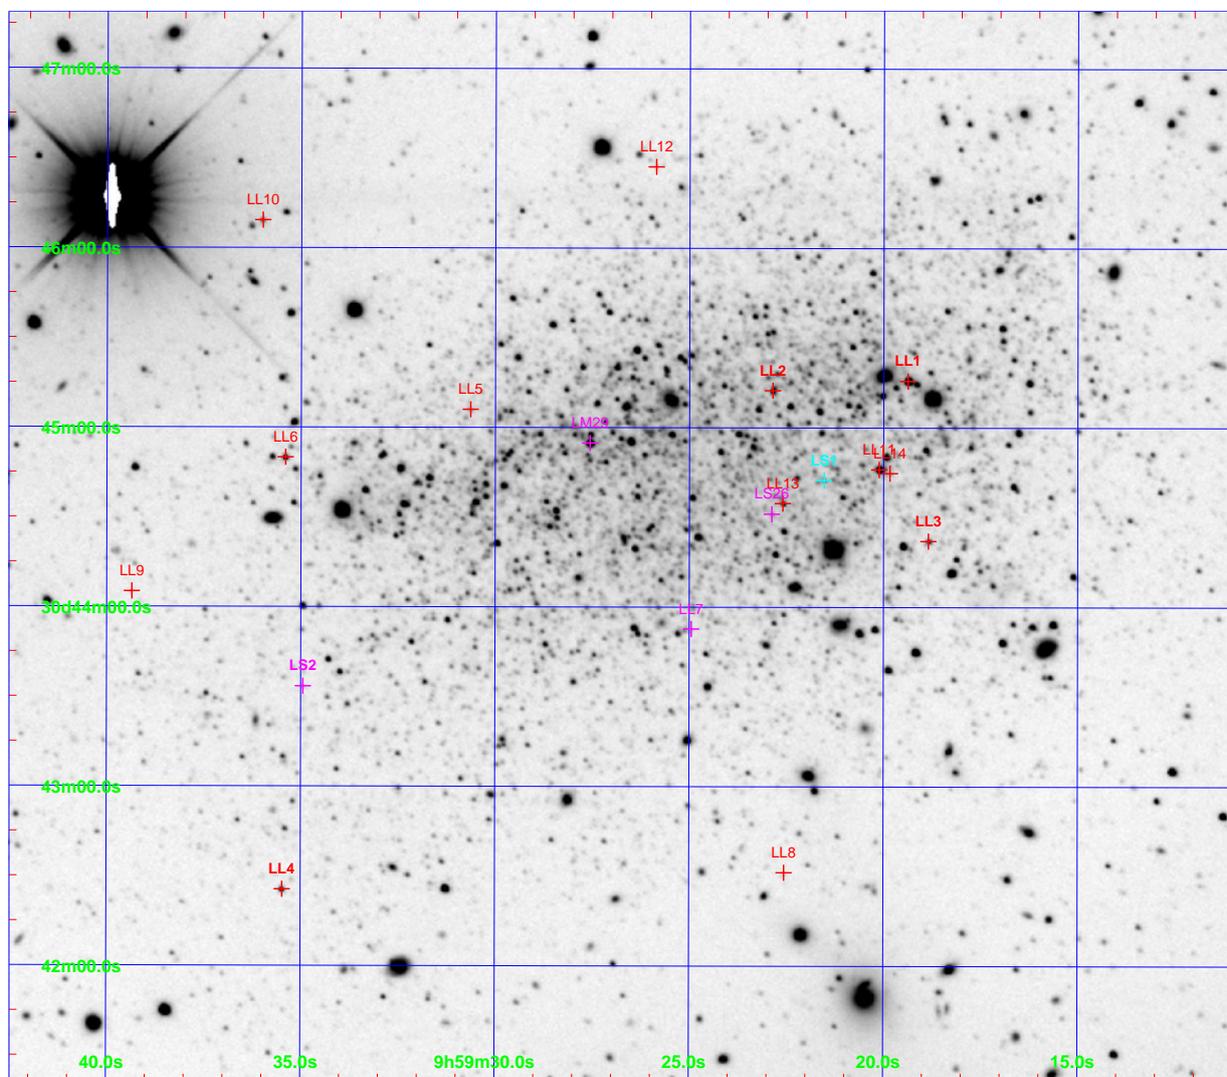

Figure G.5: Finding chart of longer period $P > 10$ d VS candidates, mostly of Tab. 5.2 but partly also from the others. Bold: high Lomb significance $p < 0.01$; red: Longer period Type II Cepheid or Mirae candidates. cyan and magenta: Candidates with interesting secondary period solutions.

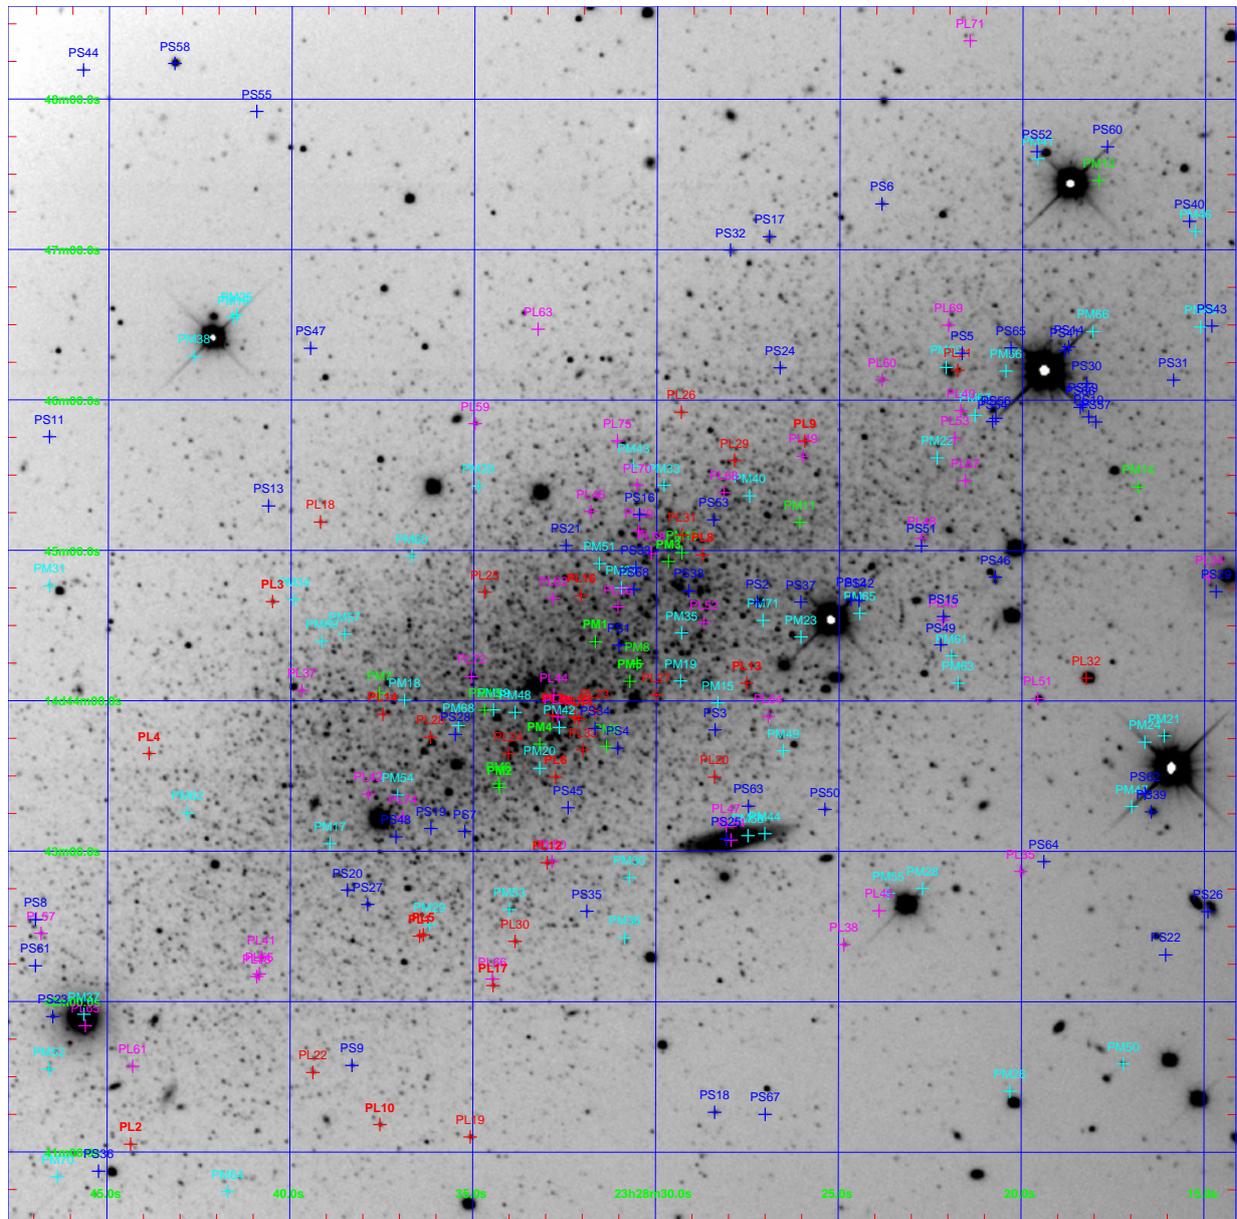

Figure G.6: Finding chart of all Pegasus Dwarf VS candidates. Bold: High Lomb significance $p < 10^{-4}$ for PM and PL candidates; blue: PS short period $P < 1$ d candidates (Tab. F.3); green: Good PM $1 \text{ d} < P < 10 \text{ d}$ VS candidates with $p < 0.01$ (Tab. 5.5) cyan: Bad PM $1 \text{ d} < P < 10 \text{ d}$ VS candidates with $p > 0.01$ (Tab. F.4); red: Good longer period Type II Cepheid or Mirae candidates with $p < 0.01$ (Tab. 5.6); magenta: Bad longer period Type II Cepheid or Mirae candidates with $p > 0.01$ (Tab. F.5).

Appendix H

Additional Light Curves

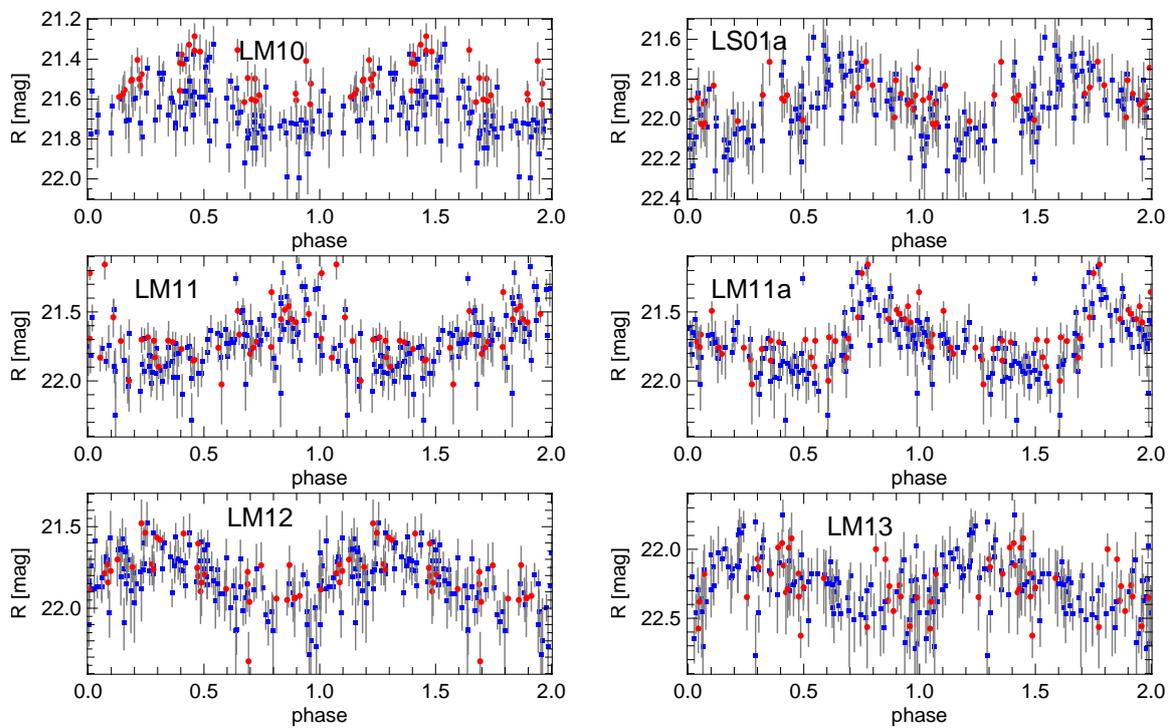

Figure H.1: Leo A 2nd best δ Cephei candidates phase convolved light curves *a*. Blue squares: WST data (Lomb detection); red circles: CA data (consistency check); coloured crosses: Data consistent with detection limit at epoch, i.e. $S/N < 1$ at either site; grey: 1σ errors.

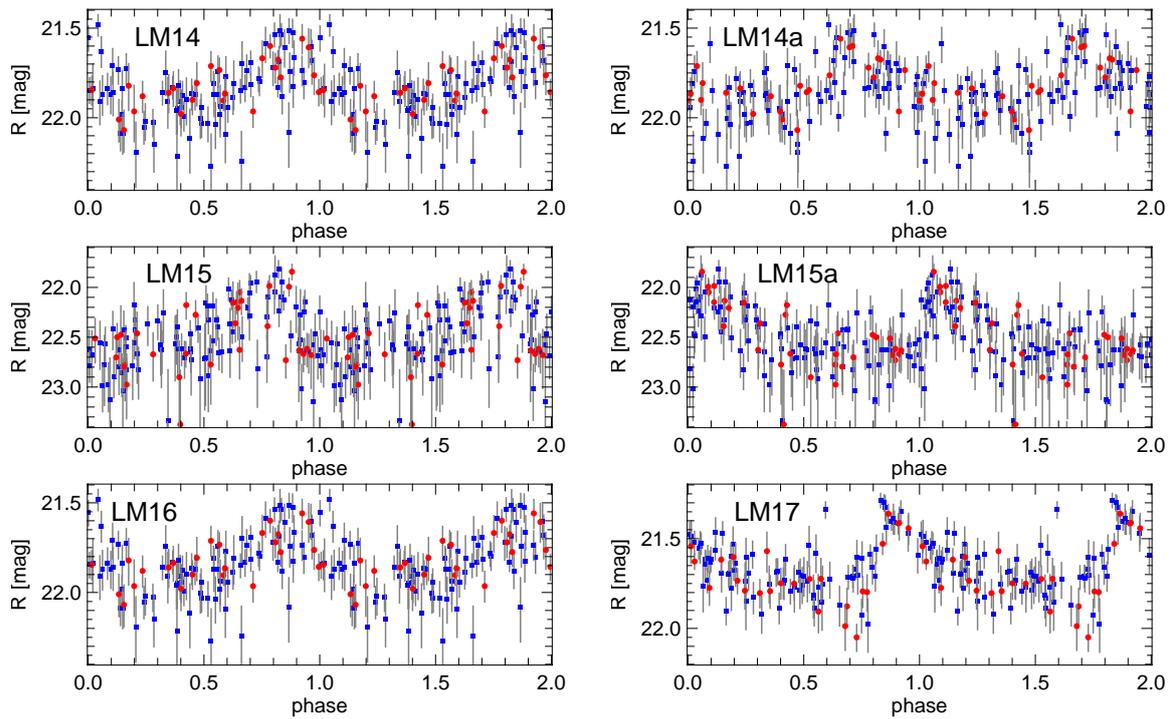

Figure H.2: Leo A 2nd best δ Cephei candidates phase convolved light curves *b*. Blue squares: WST data (Lomb detection); red circles: CA data (consistency check); coloured crosses: Data consistent with detection limit at epoch, i.e. $S/N < 1$ at either site; grey: 1σ errors.

Acknowledgements

First of all I would like to thank my thesis supervisor Ralf Bender for all his help throughout this project. Without him offering me first a PhD and, very soon into the project, even a permanent full-time position I definitely would have had to leave astronomy and abandon the project years ago. Despite some setbacks and many delays, especially in the development and building of AMiGo, he never faltered in his support for me or the project.

Ulrich Hopp, my thesis advisor, not only lead the way throughout my hitherto “career”, but more, became **the** most valued travelling companion. From writing applications for grants and observing time on telescopes, over sorting mechanical parts in the lab, to asking and answering questions (and even the silliest ones from my side); he simply was always there when needed. Not least of all I have to thank him for kicking my ... when I started to lose momentum or direction. When Jan Snigula joined our little project I immediately admired both his skills and his modesty. It soon turned out that having Jan in his team means getting things done. Since then, during hours of coding (and dome painting), he became my friend. He and his friend Chris Botzler were there “in my darkest hour” and I owe them for this as well as for many happy times we shared.

I originally started out together with Arno Riffeser, working on pixel-lensing. While our ways had to separate in science we never split up in developing and sharing software. If it was not for his difference imaging, there would be no *VarStarDwarves* at all. It began only as a “little template library” but now is the base for many a software even beyond *VarStarDwarves*, *WeCAPP*, or *MUNICS* and it was Niv Drory who showed the way. He gave me a primer and an advanced course in C++ and inspired my programming many times since.

I am deeply grateful to the staff observers at the observatory on Mt. Wendelstein. Without their countless nights spent observing for this project all this would never have been possible. I also have to thank Wolfgang Mitsch, Franz Mittermaier, Peter Well, and Johannes Koppenhöfer for all the hours they have spent on working on AMiGo. I am indebted to Heinz Barwig and Harald Lesch for their excitement about science and their enkindling way to show it.

The Deutsche Forschungs Gemeinschaft is thanked for contributing funds to my work. Special thanks go to the Calar Alto Observatory for giving us observing time at the 1.23m telescope.

At this point I would like to thank all of my friends for all the time spent together and for their friendship and support. I owe my deepest thanks to my parents, who supported me during my student years and never showed any doubt that I will finally succeed in whatever. Last but not most important I have to thank Silona Wilke that she showed ambitions beyond being just a *VarStarDwarves* trainee. Any day without her smile is a day lost.

Curriculum Vitae

Persönliche Daten

Name: Claus Alexander Gössl
Geburtsdatum: 4. März 1971
Geburtsort: Altötting
Familienstand: Ledig
Anschrift: Bad-Kissingen-Str. 58, 81671 München

Ausbildung

1977 - 1981 Grundschule in Unterneukirchen
1981 - 1990 König-Karlmann-Gymnasium in Altötting
1991 - 1998 Studium der Physik and der Ludwig-Maximilians-Universität München
1997 - 1998 Diplomarbeit an der Universitäts-Sternwarte München über "*Optimierung einer CCD-Kamera zur Beobachtung von Pixellensing in M 31*"
1998 Diplom in Physik, LMU München
1998 - 2007 Promotion in Astronomie an der LMU München über Variable Sterne in Zwerggalaxien der Lokalen Gruppe

Berufliche Tätigkeit

1990 - 1991 Wehrdienst
1998 - Wissenschaftlicher Angestellter an der LMU München, Instrumentenentwicklung für optische Teleskope, Entwicklung von Datenreduktions- und Bildverarbeitungssoftware
